## ABSTRACT

We have examined phylogenetic relationships in seven pathogenesis-related (PR) protein families. Within-family comparisons involved 79 species, 166 amino acid sequences, and 1,791 sites. For 37 species, 124 different PR isoforms were identified (an average of 3.3 per species). Thirty-one of the 37 species investigated tended to cluster together (84%). Of the 17 clusters distinguished in the seven phylogenetic trees, 10 (59%) were in agreement with their taxonomic status, ascertained at the family level. The strong similarities among the intraspecific forms, as compared to interspecific differences, argue for some kind of gene conversion, but the rare occurrence of widely different isoforms also suggests diversifying selection. PRs 1, 6, and 4 seem to be less differentiated than PRs 3, 2, 10, and 5.

*Key words:* pathogenesis-related proteins, PR, molecular evolution, plant defense.

## RESUMO

### **Implicações evolutivas da variabilidade molecular intra e interespecífica de proteínas relacionadas à patogênese**

Foram analisadas as relações filogenéticas em sete famílias de proteínas relacionadas à patogênese. As comparações dentro das famílias envolveram 79 espécies, 166 seqüências de aminoácidos e 1.791 sítios nucleotídicos. Para 37 espécies, foram identificadas 124 isoformas diferentes de PRs (uma média de 3,3 por espécie). Trinta e uma (84%) das investigadas nas 37 espécies tenderam a se agrupar. Dos 17 agrupamentos diferenciados nas sete árvores filogenéticas, 10 (59%) estiveram de acordo com a classificação taxonômica, avaliada em nível de família. A forte similaridade entre as formas intraespecíficas, quando comparadas às diferenças interespecíficas, sugere algum tipo de conversão gênica, mas a ocorrência rara de isoformas muito diferentes pode também sugerir seleção diversificadora. As PRs 1, 6 e 4 parecem ser menos diferenciadas do que as PRs 3, 2, 10 e 5.

*Palavras-chave:* proteínas relacionadas à patogênese, PRs, evolução molecular, defesa em plantas.

## INTRODUCTION

Plants have developed natural defense mechanisms acting at multiple levels in the prevention of pathogen colonization and disease.

These mechanisms involve passive and active, constitutive, and inducible elements. Defense genes can be subdivided in three classes: (a) those whose product directly changes the cell matrix properties, therefore influencing the physical barriers imposed

by the cell; (b) genes which codify proteins with antimicrobial activity or catalyze the synthesis of antibiotic products; they include enzyme inhibitors (amylases, proteinase inhibitors), toxic proteins (lectins, thionins), hydrolases (chitinases, glucanases), proteinases, and enzymes influencing the biosynthesis of oxy-phenols, tannins, ortho-chinones, and phytoalexins; and (c) those that codify pathogenesis-related (PR) proteins (Baron & Zambryski, 1995; Kombrink & Somssich, 1995; Swords *et al.*, 1997). Besides the defense genes, about 20 resistance genes have been described and analyzed. Their molecular characterizations have indicated many similarities between them, and the study of their evolutionary patterns has suggested diversifying selection, unequal crossing-over, and gene conversion as the main mechanisms which generate diversity (Michelmore & Meyers, 1998).

Pathogenesis-related proteins were first detected in the early 1970s in tobacco leaves reacting hypersensitively to tobacco mosaic virus; these were variously named until Antoniw *et al.* (1980) proposed the term used until now. The PR proteins display characteristic physico-chemical properties which help in their detection and isolation. They are: (a) very stable at low (around 3.0) pHs; (b) relatively resistant to endogenous and exogenous proteolytic enzyme action; (c) generally monomers of low molecular mass (8-100 kDa); and (d) preferentially localized in intercellular spaces. While these proteins are not generally detected in healthy plants, in those infected or submitted to specific chemical treatment they may account for 10% of the leaf content in soluble proteins (Stintzi *et al.*, 1993).

At the 3<sup>rd</sup> International Workshop on PR proteins (Arolla, Switzerland, August 16-20, 1992) it was agreed that common classification and nomenclature should be used. Specifically, five families were recognized, based on different criteria. The numbering was according to relative mobility in nondenaturing gel systems. Those classified in a given family are serologically related, have very similar molecular weights, and share highly uniform amino acid sequences (Linthorst, 1991; Cutt & Klessig, 1992).

With investigative progress, new proteins have been identified, and at present 14 PR families are officially recognized (Van Loon & Van Strien, 1999), although new proteins with potential anti-pathogenic action continue to be described at a rapid pace.

Increased interest in this biological system arose as it was verified that PRs are not restricted to plants, but are also present in fungi and animals (invertebrate and vertebrate), constituting the so-called "PR protein superfamily". Its members include proteins from fungi (*Saccharomyces*, *Schizophyllum*) and nematodes (*Caenorhabditis*); antigen 5, one major vespid venom allergen and an antigen 5-related protein from *Drosophila melanogaster*; helothermine, from a lizard venom; mammalian Tpx-1 testis-specific protein and sperm-coating glycoprotein Scg; and human specific granule protein 28 from neutrophils, P25TI trypsin inhibitor of neuroblastoma and glioblastoma cells, and glioma pathogenesis-related GliPr (Schreiber *et al.*, 1997; Szyperki *et al.*, 1998; Yamakawa *et al.*, 1998).

Considering their ubiquity and importance, it is surprising to verify that no systematic molecular comparison of these proteins has been undertaken, the notable exception being the thorough analysis performed by Wen *et al.* (1997) on the *Bet v 1* homologues (PR 10), and by Bishop *et al.* (2000) on the chitinases of PR8. Here we consider the molecular relationships of PR10 and six other PR families.

## MATERIALS AND METHODS

The amino acid sequences considered were obtained from the Prosite data bank (<http://expasy.hcuge.ch/sprot/prositc.html>) which groups all protein sequences described in Swiss-Prot (<http://expasy.hcuge.ch/sprot/sprot-top.html>), in accordance with their signatures (characteristic sequences of each protein group). The alignment was made using the ClustalW program, and Kimura's (1983) genetic distance was determined among the sequences. Phylogenetic trees were obtained by the neighbor-joining method (Saitou & Nei, 1987). Matrices of genetic distances and the phylogenies were constructed using the Treecon for Windows program.

## RESULTS

The proteins considered, classified in seven families, are listed in Tables 1-7; the corresponding dendrograms are shown in Figs. 1-7. Each PR family will be considered separately, and at the end we will determine what generalizations can be made.

TABLE 1

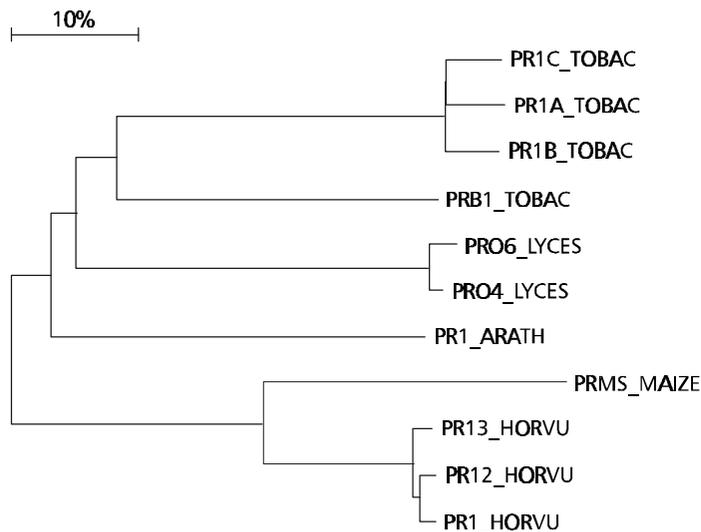

Fig. 1 — Phylogenetic tree of the PR1 proteins.

Eleven PR1 sequences comprising 172 sites each were evaluated. They occur in five species, distributed among three taxonomic families. Three species present a total of nine isoforms, all of them occurring together in the dendrogram. The two clusters observed are formed by proteins from species belonging to the same taxonomic family (upper, Solanaceae; lower, Gramineae). The PR1 from *Arabidopsis thaliana* cluster with those from the Solanaceae.

For PR2, 35 sequences, and 344 sites were compared (Table 2 and Fig. 2). They are distributed along 14 species, classified in six families. Seven species present 28 multiple PR forms; of these, the

isoforms of *Nicotiana plumbaginifolia* (NICPL), *Solanum tuberosum* (SOLTU), and *Hordeum sativum* (HORVU) occur together. Those from *Nicotiana tabacum* (TOBAC) form two main groups, but those from *Glycine max* (SOYBN), *Arabidopsis thaliana* (ARATH), and *Solanum lycopersicum* (LYCES) occur separately. Of the three clusters formed, one includes two subclusters of Solanaceae, but the third subcluster is mixed (shows proteins from different taxonomic families).

The second cluster is formed basically by Gramineae proteins, while the third is mixed (ARATH and WHEAT, the latter from *Triticum aestivum*).

<sup>1</sup>Accession code to the Swiss-Prot.

A total of 27 PR3 sequences comprising 391 sites could be assembled (Table 3 and Fig. 3). They are present in 14 species, grouped in seven families. Seven of the species present 20 isoforms, and of these ORYSA (from *Oryza sativa*) and MAIZE (*Zea mays*) occur together. TOBAC, LYCES, and PHAVU (the latter from *Phaseolus vulgaris*) are each present in two different clusters, while BRANA (from *Brassica napus*), and POPTR (*Populus trichocarpa*) appear in different clusters. Two main clusters are visualized, the first (upper part of the figure), larger, subdivided in four subclusters. The first and fourth subclusters are composed by Solanaceae and the third by Gramineae proteins. The second is mixed (BRANA + ARATH + PHAVU). The other cluster is also mixed (DIOJA, from *Dioscorea japonica*, + PHAVU + BRANA + MAIZE).

Less information is available for PR4. The results include nine sequences (217 sites compared),

distributed among seven species belonging to five families (Table 4 and Fig. 4). Two species show four isoforms which occur together. Little differentiation was observed, with the *Hordeum* (HORVU) and *Glycine* (SOYBN) proteins being set somewhat apart.

A total of 26 PR5 sequences comprising 250 sites, in 12 species of six families, were compared (Table 5 and Fig. 5). The 22 multiple forms from the same species (eight considered) generally occur together, with those from *Arabidopsis* (ARATH) and *Nicotiana* (TOBAC) clustering in two groups. Two main clusters can be observed, the first (upper part of the figure) presenting two differentiated subclusters. The one at the top is composed mainly by Solanaceae, while the second unites ARATH with PRUAV (from *Prunus avium*, classified in a different taxonomic family). The second cluster is composed by Gramineae proteins.

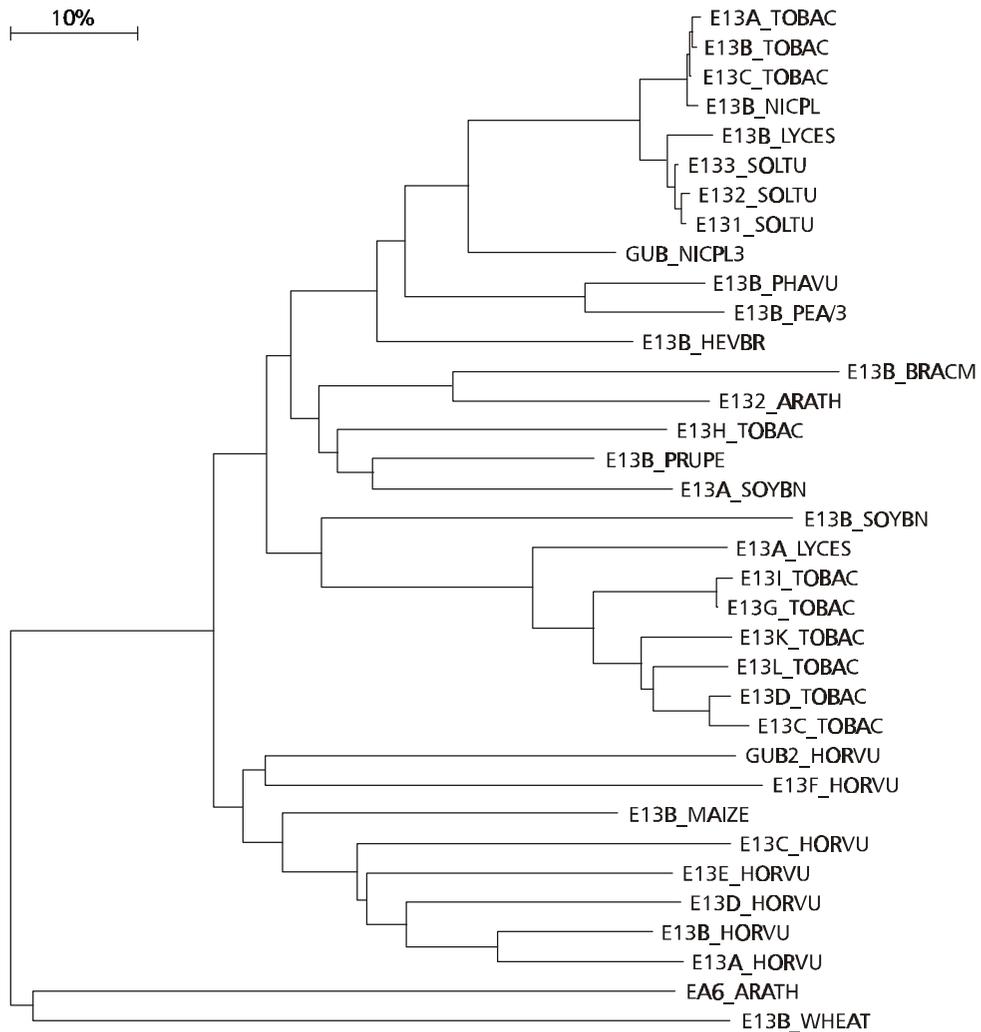

Fig. 2 — Phylogenetic tree of the PR2 proteins.

Thirty PR6 sequences with 255 sites, found in 16 species classified in seven families were compared (Table 6 and Fig. 6). The 18 multiple forms from the four species in which they occur are generally found together (SOYBN, SOLTU, from *Solanum tuberosum*, IPOBA, from *Ipomoea batatas*), while those from *Psophocarpus tetragonolobus* are distributed in two groups of two, with another (ALB1\_PSOTE) quite separated. Three clusters can be distinguished. The first is composed by Fabaceae proteins, the second by *Solanum tuberosum* forms, while in the third a subcluster is formed by Gramineae proteins; the others show

proteins of species from different families. For PR10 there is complete congruence with the taxonomic classification (Table 7 and Fig. 7). Twenty-eight sequences with 162 sites, observed in 11 species which belong to five families, were studied. Six species presented 23 isoforms, and all clustered together, especially BTVE, which showed little differentiation. In the three clusters formed, the first and third are respectively comprised by Betulaceae and Fabaceae proteins. In the second, one subcluster is formed by Apiaceae and the other by Solanaceae proteins, ASPOF, from *Asparagus officinalis*, forming a separate branch.

### General overview

We, therefore, examined seven PR families. Within-family comparisons involved 79 species, 166 sequences, and 1,791 sites. For 37 species, 124 different PR isoforms were identified (an average of 3.3 per species). Thirty-one of those investigated in the 37 species tended to cluster together (84%). Of the 17 clusters distinguished in the seven phylogenetic trees, 10 (59%) were clearly in agreement with the taxonomy as evaluated at the family level.

What comparisons can be made among the PR families? The average genetic distances obtained clearly separates them into two groups (despite the expected high standard deviations) apparently unrelated to their functions: group 1: PR1 (function unknown),  $0.02 \pm 0.02$ ; PR 6 (proteinase inhibitors),  $0.10 \pm 0.03$ ; and PR4 (chitinases),  $0.26 \pm 0.09$ ; group 2: PR3 (chitinases),  $0.73 \pm 0.32$ ; PR2 ( $\beta$ -1,3-glucanases),  $0.76 \pm 0.32$ ; PR10 (birch allergen Bet v 1-related),  $0.77 \pm 0.43$ ; and PR5 (thaumatin-like),  $0.98 \pm 0.50$ .

### DISCUSSION

The genetic system underlying the PR proteins clearly qualifies for classification as a multigene family, since there is a multiplicity of forms which occur both within and between species, with a general molecular similarity among them. The mechanisms that may give origin to such families have been discussed by Li (1997); these include saltatory replication, unequal crossing-over, replication slippage, gene conversion, and duplicative transposition. Without direct evidence it is impossible, at the moment, to indicate any one of them as responsible for the PR system.

The degree of variability found, however, allows some inferences about the evolution of these forms. Thus, the strong similarities among the intraspecific isoforms (84% of them clustered together in the phylogenetic trees) as compared to the interspecific comparisons (only about half of the cases were congruent with their taxonomic status as assessed at the family level) suggest a process of gene conversion (Zimmer *et al.*, 1980).

Equally interesting, however, are the cases in which the isoforms did not cluster together. Marked differences, for instance, were observed between the PR2 isoforms of *Arabidopsis thaliana* ARATH\_E132 and ARATH\_EA6 (genetic distance of 1.16), and the PR3 isoforms of *Brassica napus* BRANA\_CHI2 and BRANA\_CHI4 (genetic distance of 1.06). Less pronounced but still important, are the differences between the PR2 isoforms of *Glycine max*

E13A\_SOYBN and E13B\_SOYBN (genetic distance of 0.82), and the PR3 isoforms of *Populus trichocarpa*, CHIB\_POPTR and CHI8\_POPTR (genetic distance of 0.75). Due to the special characteristics of this genetic system, the occurrence of diversifying selection between these forms does not seem unreasonable. We have considered this question in detail in another study (Scherer *et al.*, 2003).

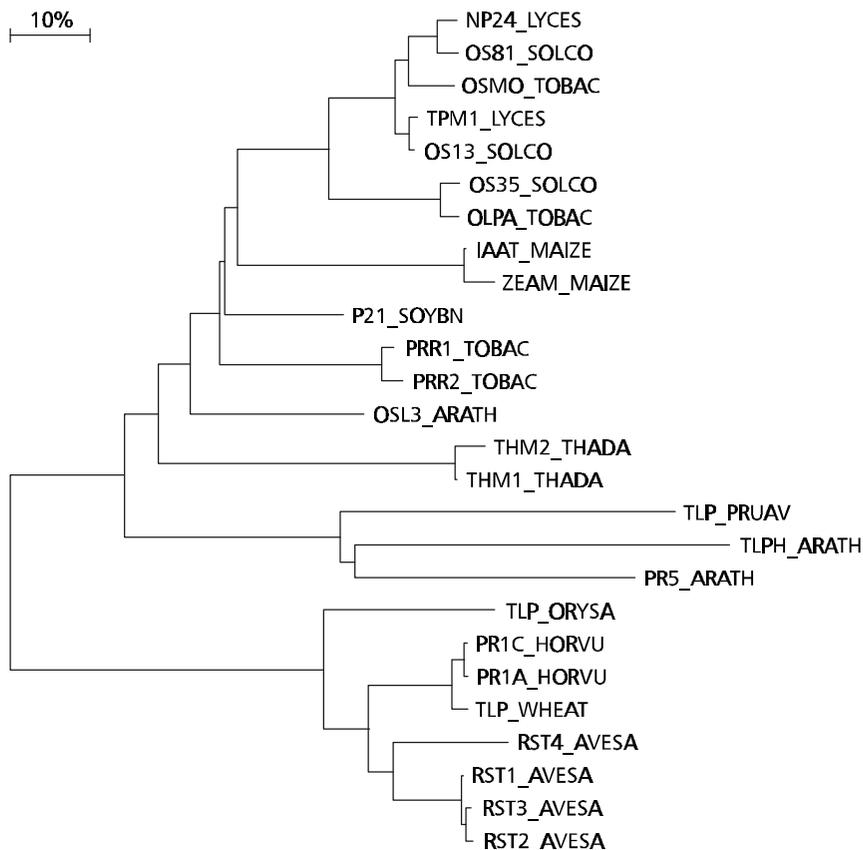

Fig. 5 — Phylogenetic tree of the PR5 proteins.

Our results also suggest that PRs 1, 6, and 4 are less differentiated than PRs 3, 2, 10, and 5. In terms of differentiating mechanisms, Michelmore & Meyers' (1998) model for resistance genes may well also apply to PR genes. It proposes initial diversification through interallelic recombination and gene conversion, followed by divergent evolution of individual genes and a birth-and-death process.

Some of the PRs considered here have been phylogenetically analysed by other authors. The extended analysis of 67 PR10 sequences performed by Wen *et al.* (1997) at the nucleotide level has already been mentioned. Hoffmann-Sommergruber *et al.* (1997) also considered seven amino acid sequences of this same family, from an equivalent number of species.

The present analysis generally agrees with the relationships those authors obtained. On the other hand, the study of Szyperski *et al.* (1998) was mainly concerned with a global genealogical tree of the PR protein superfamily, which includes the plant PR1.

They considered five protein sequences of the latter in an equivalent number of species and obtained phylogenetic relationships that have basically been confirmed by us.

It is not yet clear how the PR protein superfamily evolved. But Szyperski *et al.* (1998) have found that human GliPR and plant PR1 proteins seem to operate according to the same molecular mechanism, suggesting a functional link between the human immune and plant defense systems. Convergent evolution of two independent ancestors is unlikely. Therefore, the other possibilities are that either P14a (the PR1 protein studied) and GliPR arose from a common ancestor at a very early stage of evolution, or that horizontal transfer occurred at a much later stage.

At present it is impossible to decide between these two hypotheses. But the evolutionary importance of transposons is increasingly being recognized, as exemplified by the studies of Clegg *et al.* (1997) and Grandbastien (1998).

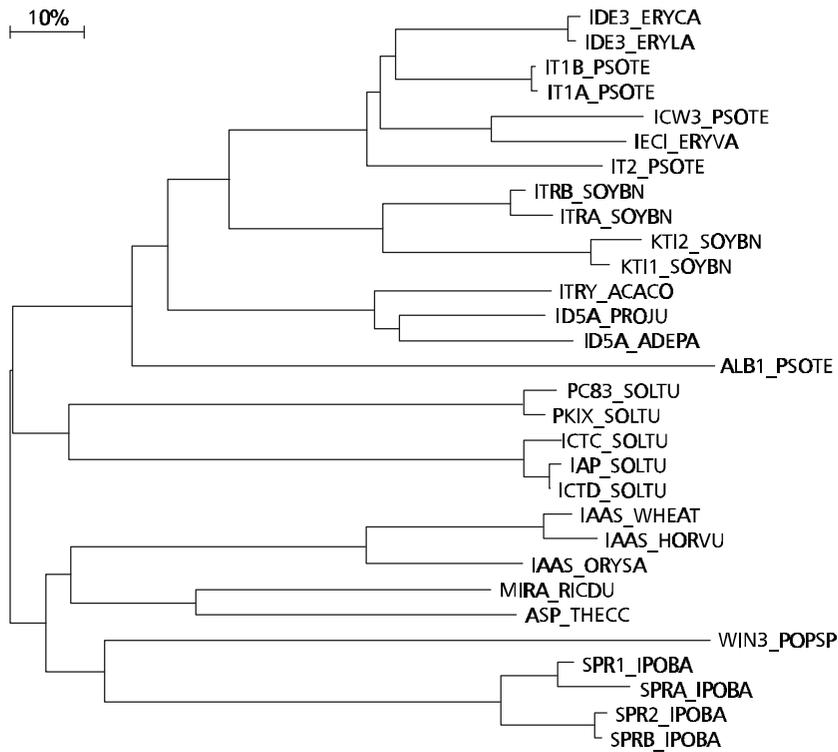

Fig. 6 — Phylogenetic tree of the PR6 proteins.

As was stressed by Stintzi *et al.* (1993) and Swords *et al.* (1997), understanding how plants resist outside insults may open the way for genetically-engineered species with improved resistance against fungi and bacteria, obtained by transformation with PR genes. The aim could be PR combinations that would either act synergistically, or differentially attack microbes. To achieve this goal, it is important to know the type of variability present within and between species, as well as the differences that exist between different family sets. The present study is a modest contribution in that direction.
