(Received 10 September 2002; revised 2 January 2003; accepted 2 January 2003)

**SUMMARY**

The *Echinococcus granulosus* genome was searched for microsatellites using 8 different repeated oligonucleotides as probes (GT15, CT15, AT15, CG15, CAT15, CAA15, CGG15 and CAT15). Southern blot experiments revealed that DNA regions containing GT, CAA, CAT and CT repeats are the most frequent in the *E. granulosus* genome. AT and CG probes showed no hybridization signal. Two loci containing CA/GT (Egmsca1 and Egmsca2) and 1 locus containing GA/CT (Egmsca1) repeats were cloned and sequenced. The locus Egmsca1 was analysed in 73 isolates from Brazil and Argentina whose strains were previously characterized. Brazilian isolates from cattle strain and Argentinean isolates from camel strain were monomorphic and shared the allele (CA)10. Argentinean isolates of sheep and Tasmanian sheep strains shared 2 alleles [(CA)10 and (CA)11] with Brazilian isolates of sheep strain. The allele (CA)10 was found only in Brazilian isolates of sheep strain at a low frequency. The Brazilian and the Argentinean sheep strain populations were tested for the Hardy-Weinberg equilibrium, and only the former was in agreement with the expectations. No polymorphism was found among individual protoscoleces from a single hydatid cyst, validating the utilization of pooled protoscoleces from 1 cyst, grouped as an isolate, in population studies. This work describes for the first time the isolation and characterization of microsatellites from *E. granulosus*.

Key words: *Echinococcus granulosus*, Cestoda, microsatellite markers.

**INTRODUCTION**

*Echinococcus granulosus* is a small endoparasitic flatworm causative of hydatid disease in intermediate hosts (wild and domestic herbivores and also man) and of echinococcosis in definitive hosts (canids). The hydatid disease is one of the most important zoonoses (Thompson & Limbery, 1995). Although control programmes against human hydatid disease have been established in some countries and effective strategic controls are available, the parasite has still a wide geographical distribution affecting many countries of all continents (Eckert, Conraths & Tackmann, 2000).

Microsatellites are tandemly repeated DNA segments, with short repeat units (≤6 bp), which are usually polymorphic in number (Tautz, 1989; Weber & May, 1989; Litt & Lutty, 1989). Because of their high abundance, widespread distribution and high heterozygosities in the genomes of various organisms (Stallings et al. 1991), microsatellites are useful in studies of population structure, molecular epidemiology and genomic mapping.

Although a variety of microsatellite loci have been described in parasites, we noticed only 2 such studies in Cestoda. Pentanucleotide repeats were found within the *E. multilocularis* U1 snRNA gene complexes, which discriminated parasites from different localities (Bretagne et al. 1996). Also, 5 polymorphic loci were isolated from the tapeworm *Schistoscephalus solidus* (Binz et al. 2000). No microsatellite markers have been described for *E. granulosus* to date. Since the species has a high degree of differentiation, and strains are supposed to differ in developmental, transmission and other features, microsatellites would be valuable markers for epidemiological and clinical studies. In this work the presence and abundance of microsatellites in *E. granulosus* genome was analysed...

by Southern hybridizations. We also isolated and characterized 2 CA and 1 GA repeat loci. We used one of the CA loci for a preliminary population analysis.

MATERIALS AND METHODS

Southern hybridization

Total DNA obtained from protoscoleces of a single hydatid cyst was digested with AluI, TaqI, RsaI, EcoRI or HindIII, electrophoresed in a 0.8% agarose gel and transferred to nylon membranes (Hybond N*, Amersham-Pharmacia). The hybridization was carried out according to Sambrook & Russell (2001). Eight different aP-labelled oligoprobes (Table 1) were used for hybridization with DNA of E. granulosus. The temperature of hybridization and the stringency of washing conditions varied according to the Tm (melting temperature) of each oligonucleotide (Table 1).

Microsatellite isolation

(CA)$_n$ (GA)$_m$ and (TA)$_m$ repeats were isolated as described earlier (Refseth, Fangan & Jakobsen, 1997; Oliveira et al. 1998), with some modifications. Genomic DNA was digested with TaqI (Gibco BRL) and 500 ng of fragments were ligated to 50 pmoles of an adapter at 16 °C overnight using 1 unit of T4 DNA ligase (Gibco BRL). Then 100 ng of the ligation product were mixed with 20 pmoles of one of the biotinylated oligonucleotides GATGATCCGAC-GCAT(CA)$_{12}$, GATGATCCGACGCAT(GA)$_{12}$ or GATGATCCGACGCAT(TA)$_{12}$ in 50 μl of TE buffer (10 mM Tris–HCl, pH 8.0; 1 mM EDTA, pH 8.0) containing 2 μM of the TaqI-20 mer oligonucleotide to avoid hairpin formation. The mixture was heated to 95 °C for 10 min and then annealed at 60 °C (or 40 °C for AT-repeats) for 1 min. The fragments containing the repeats were captured by streptavidin-coated magnetic beads (Dynabeads M280, Dynal) and amplified by PCR (polymerase chain reaction) in a 50 μl reaction volume containing 10 pmoles of the adapter oligonucleotide, 2-5 units of Taq DNA polymerase (Cenbiot), 100 μM of each dNTP and Taq buffer (10 mM Tris–HCl, 50 mM KCl, 4 mM MgCl$_2$). The samples were incubated at 94 °C for 3 min and subjected to 23 cycles consisting of 1 min at 94 °C for denaturation and 3 min at 72 °C for annealing and extension and then incubated for a final extension for 5 min at 72 °C. PCR products were purified in GFX columns (Amersham-Pharmacia) and cloned in the pGEM-T Easy Vector (Promega). Plasmid inserts were sequenced using the DYEnamic Dye Terminator Cycle Sequencing kit for MegaBACE (Amersham-Pharmacia).

E. granulosus isolates

A total of 73 E. granulosus metacestode isolates (Table 2) from the Southern region of Brazil and from different Argentinean provinces were analyzed.

Strains were identified as follows. In a previous study, Kamenetzky et al. (2002) sequenced the mitochondrial cytochrome c oxidase I gene and compared their results with the published sequences (Bowles, Blair & McManus, 1995). In another study, the strains from Brazilian samples were identified by SSCP of 6 different DNA segments: the non-coding introns from genes ActII and Hbx2, part of the coding region of the nuclear antigen B, part of the mitochondrial NADH dehydrogenase I gene, the non-coding 5’ flanking region of the cytosolic MDH (malate dehydrogenase) gene and the 3’ flanking region of Ag6 (a calcium-binding protein) gene. The obtained patterns were compared to reference isolates from each strain (Haag et al. 1999).

DNA amplification and analysis of microsatellite loci

Primers were designed complementary to the sequences flanking the CA/GT (Egmsca1-F: 5’ CGAAAGTGATGACAAACCAA 3’ and Egmsca1-R: 5’ GCTTGATGGAGATGAGGTCG 3’).
and GA/CT repeats (Egmsga1-F: 5′ TGACGGC-GATGATGAGATAG 3′ and Egmsga1-R: 5′ CCT-TGCCACACGCTACACTG 3′). PCR was carried out in a 50 μl reaction volume containing 10–20 ng of the genomic DNA from protoscoleces of a single hydatid cyst, 20 pmoles of each primer, 10 mM Tris–HCl, pH 8.5, 50 mM KCl, 1.5 mM MgCl₂, 100 μM of each dNTP and 2.5U Taq DNA polymerase. Control reactions with bovine, ovine and human DNAs were carried out to certify that no contamination with host DNA was present in templates. PCR products were electrophoresed in 40 cm long 8% polyacrilamide gels and visualized by AgNO₃ staining. The different alleles found were manually sequenced to verify the number of repeats, utilizing the Thermo-Sequenase Radiolabeled Terminator Cycle Sequencing Kit (Amersham-Pharmacia).

Microsatellite analysis in individual protoscoleces from single hydatid cysts

In order to analyse possible genetic variation among individual protoscoleces from a single hydatid cyst, protoscoleces from 6 cysts were isolated under a microscope, added to 25 μl of distilled H₂O, incubated with 2 μg of proteinase K at 50 °C for 1 h and at 95 °C for 20 min, under mineral oil. PCR was carried out in a 50 μl reaction volume containing the lysed protoscolex, 10 pmoles of each Egmsca1-F and Egmsca1-R primers, 10 mM Tris–HCl, pH 8.5, 50 mM KCl, 1.5 mM MgCl₂, 100 μM of each dNTP and 2.5U Taq DNA polymerase. PCR products were electrophoresed in 40 cm long 8% polyacrilamide gels and visualized by AgNO₃ staining. The different alleles found were manually sequenced to verify the number of repeats, utilizing the Thermo-Sequenase Radiolabeled Terminator Cycle Sequencing Kit (Amersham-Pharmacia).

Statistical analysis

All statistical analyses were performed with Genepop (v3.1b, a program developed by Raymond & Rousset (1995a). Only the Brazilian and Argentinean populations from sheep strain (with n > 10) were tested. Hardy-Weinberg proportions were tested by an exact test on contingency tables (Weir, 1990). Within this test the P-value corresponds to the sum of probabilities of all tables (with the same allelic counts) with the same or lower probability than the probability of the observed samples, which is used to define the rejection zone. A Markov chain is used to explore adequately the space of possible tables.

Tests for genic and genotypic differentiation (concerned with the distribution of alleles and genotypes in the various populations) were performed on contingency tables by a Fisher exact test (Raymond & Rousset, 1995b) and a G-based test (Goudet et al. 1996). Fis and Fst estimations were calculated following Weir & Cockerham (1984).

RESULTS

Detection of microsatellites in the E. granulosus genome

The hybridization of 6 different probes [(GT)₁₅, (CT)₁₅, (CAT)₁₀, (CAA)₁₀, (CGG)₁₀, (CATA)₁₀] to E. granulosus genomic DNA generated a pattern of single or multiple bands ranging from approximately 0.3 to 10 kb (Fig. 1). The probes (GT)₁₅, (CAA)₁₀, (CATA)₁₀ and (CT)₁₀ showed the highest number of hybridizing bands, independently of the restriction enzyme used. Among these repeated sequences, GT and CAA were the most abundant type of microsatellites in the E. granulosus genome, followed by CATA and CT repeats.

The hybridization with the probes (CAT)₁₀ and (CGG)₁₀ generated only a small number of bands. No hybridization was observed with probes (AT)₁₀ and (CG)₁₀ (data not shown).

Isolation and characterization of sequences containing dinucleotide repeats

Several clones containing perfect CA and GA-repeats were isolated, but only 3 of these presented both flanking sequences (Egmsca1, Egmsca2 and Egmsga1) (Fig. 2). The other clones presented 1 flanking sequence and 1 end with the sequence
GATGATCCGACGCAT, due to internal priming of the biotinylated oligonucleotide leaking from the magnetic beads. From the 3 complete isolated sequences, 1 contained the microsatellite near to an insert end, impeding the design of a primer on this flanking extremity (Egmsca2). Primer pairs were designed to amplify Egmsca1 and Egmsga1 loci (Fig. 2).

Attempts to isolate TA-repeats were made, despite the negative result in the Southern experiment, to ascertain a possible failure in hybridization with the (TA)$_{15}$ probe, related to its low Tm. However, no clones were isolated containing this type of repeat.

Polymorphism of the Egmsca1 locus

No polymorphism was found among 150 protoscoleces from a single hydatid cyst. Twenty protoscoleces from 5 additional cysts were also analysed, and no variation was found. All individuals were homozygotes for Egmsca1 locus, with a (CA)$_7$.
(1 cyst), (CA)₈ (1 cyst) or (CA)₁₀ repeat (4 cysts), as revealed by sequencing.

Four alleles were found among the 73 studied isolates, which were confirmed by sequencing the PCR products from several homozygote and heterozygote individuals: (CA)₇, (CA)₈, (CA)₁₀ and (CA)₁₁ (Fig. 3).

The allelic frequencies are shown in Table 3. The allele (CA)₇ was found only in cattle and camel strains. The sheep and the Tasmanian sheep strains shared the alleles (CA)₈ and (CA)₁₀. The allele (CA)₁₁ was detected only in the sheep strain isolates from Brazil.

Microsatellite data from the Egmsca1 locus showed significant heterozygote deficiency in the Argentinean sheep strain population (P<0.05). The Brazilian sheep strain population agreed with Hardy-Weinberg genotype expectations (P>0.05). The genotype frequencies and heterozygosities for each population are presented in Table 4.

No genetic differentiation was detected between the Brazilian and Argentinean sheep strain populations (P>0.05). The values of Fis and Fst were, respectively, 0.48 and −0.02, considering the whole sample of sheep strain isolates separated into 2 populations (Brazil and Argentina).

Despite our attempts to optimize PCR conditions, the analyses on the Egmsga1 locus resulted in a high number of amplification bands, and were not used in the population study.

**DISCUSSION**

The isolation of microsatellites and their flanking sequences from genomes is frequently a laborious and expensive exercise, except for those organisms whose genomes have been completely sequenced or from which a high number of sequences has been deposited in Data Banks. The analysis of microsatellites by Southern blot using repeated oligonucleotides as probes can provide valuable information before the repeat isolation.
Among the repeated oligonucleotides we used for hybridization with DNA of *E. granulosus*, the probes (GT)$_{15}$, (CAA)$_{10}$, (CATA)$_{10}$ and (CT)$_{15}$ showed the greatest number of hybridized bands in *E. granulosus*. GT repeats (or CA) have been reported as the most frequent microsatellite motifs in several animal genomes (Tautz, 1989; Weber & May, 1989; Stallings et al., 1991; Katti, Ranjekar & Gupta, 2001). AAC microsatellites are among the most frequent trinucleotide repeats found in the human, *Drosophila* and yeast genomes, and CATA microsatellites are the most frequent tetranucleotide repeats found in *Drosophila* (Katti et al., 2001). We conclude that the (AT)$_{15}$ and (CG)$_{15}$ repeats are absent in the *E. granulosus* genome, or present at very low frequencies, because no hybridization signal was observed for these probes. A lack of CG repeats was reported in human, mouse, *Caenorhabditis elegans*, *Drosophila melanogaster*, *Arabidopsis thaliana* and yeast genomes (Dokholyan et al., 2000; Katti et al., 2001). Moreover, our attempts to isolate (TA)$_n$ repeats have all failed. We were able to isolate CA/GT and GA/CT microsatellites, proving that the analysis by genomic Southern blot is helpful to study their distribution and abundance as a previous step in the isolation strategy.

replication slippage during the asexual reproduction stage of *E. granulosus* could lead to differences among protoscoleces. The Egmsca1 locus was successfully amplified in 150 protoscoleces taken at random from 1 single cyst and no genetic differences were observed. Twenty protoscoleces isolated from each of 5 additional cysts showed no within-cyst differentiation too. These results validate the use of protoscoleces from a whole hydatid cyst in studies of *E. granulosus* population genetics, utilizing microsatellites as molecular markers.

The Egmsca1 genotype distributions confirmed that both selfing and outcrossing occur in *E. granulosus*, as reported by other authors (Lymbery, Thompson & Hobbs, 1990; Haag et al. 1999). The negative value found for Fst in this locus indicates that the Brazilian and Argentinean populations from the sheep strain are not structured. The analysis of a larger number of microsatellite loci will be required to enhance the sensitivity of detection of within-strain geographical differences. Indeed, only one allele [(CA)₅] was shared by the cattle and camel strains. The phylogenetic relatedness of these strains was previously shown in three parsimonious trees constructed from mitochondrial data sets (Bowles et al. 1995).

In conclusion, microsatellites are fully distributed in *E. granulosus* genome, and their polymorphism is useful to detect strain as well as some geographical differences. For this reason, we are working on the isolation and characterization of more loci, which could be used as a panel for different studies on population structure, genetic epidemiology and diagnosis of hydatid disease.

M.L.B.-S. was a recipient of a fellowship from CNPq (Brazil) and subsequently from CAPES (Brazil). This work was supported by CNPq, PADCT/CNPq and FAPERGS (Brazil). We would like to thank Dr Mara C. Rosenzvit for the critical reading of the manuscript.
