Introduction: Connective tissue diseases represent a rare, heterogeneous group of diseases that commonly impair the function of many organs.

Objectives: Aim of this study was to determine whether a history of connective tissue disease has any impact on postoperative morbidity and mortality in patients who undergo cardiac surgery under the use of cardiopulmonary bypass.

Methods: We retrospectively reviewed our electronic database of 1618 consecutive cardiac surgery patients from May 2012 to March 2016. We analyzed the postoperative outcome indices of cardiac surgical patients with a history of connective tissue disease.

Results: A total of 15 (5 females) patients were identified (group A): 12 rheumatoid arthritis, 2 ankylosing spondylitis, 1 psoriatic arthritis. Other conditions included psoriasis, endocarditis, lupus, gout, and ankylosis. Most patients underwent coronary artery bypass and 2 operations on thoracic aorta. Comparing with the rest of the cohort (group B), the study group patients were older (69.6 ± 7 vs 65.2 ± 10), their average pre-op mean ejection fraction was 57.3 ± 10 % vs 55.6 ± 11 % and their pre-op eGFR (MDRD) was 76.2 ± 23 vs 73.7 ± 23 mL/min/1.73 m2. Pulmonary hypertension-defined as pre-op doppler systolic pulmonary pressure > 30 mmHg was found in 5/15 patients (36.6 % vs 22.49 %, p = 0.34). Median duration of mechanical ventilation was 11 hours for group A vs 7 hours for group B. Transfusion with > 3 red blood units was required in 5/15 (36.6 % vs 23.4 %, p = 0.36). Post-op low cardiac output syndrome developed in 2/15 (13.3 % vs 5.49 %, p = 0.43). Acute kidney injury defined by RIFLE criteria complicated 2/15 patients (13.3 % vs 15.6 %, p = 0.78). Post-op atrial fibrillation developed in 7/15 (46.6 % vs 33.6 %, p = 0.31). One patient required non invasive ventilation for post-op respiratory failure. Median ICU days were 2 in both groups. No patient of the study group developed sternal wound infection or had prolonged (>24 hours) mechanical ventilation while hospital mortality was 0 %.

Conclusions: According to the results of this single-center retrospective study, cardiac surgery procedures could be performed safely in patients with a history of connective tissue disease.

Red cell distribution width at hospital discharge and post-hospital outcomes in ICU survivors with chronic liver disease
K.E. Hathorn1, S.W. Purcell2, C.M. Horkan1, F.K. Gibbons3, K.B. Christopher4,5
1University of Colorado, Division of Pulmonary Sciences and Critical Care Medicine, Boulder, USA; 2Massachusetts General Hospital, Pulmonary and Critical Care Medicine, Boston, USA; 3Brigham and Women’s Hospital, Renal Division, Boston, USA; 4Brigham and Women’s Hospital, Channing Division of Network Medicine, Boston, USA

Introduction: Red Cell Distribution width (RDW) is associated with mortality and bloodstream infection risk in the critically ill. In survivors of critical care with chronic liver disease (CLD) it is not known if RDW can predict subsequent risk of all-cause mortality following hospital discharge.

Objectives: We hypothesized that an increase in RDW at hospital discharge in CLD patients who received critical care would be associated with increased mortality following hospital discharge.

Methods: We performed a two center observational study of patients treated in medical and surgical intensive care units in Boston, Massachusetts. We studied 4,442 patients, age ≥ 18 years, who had chronic liver disease, received critical care between 1998 and 2012 and survived hospitalization. The exposure of interest was RDW within 24 hours of hospital discharge and categorized a priori as ≤ 13.3 %, 13.3-14.0 %, 14.0-14.7 %, 14.7-15.8 %, 15.8-17.0 % and >17.0 %. The primary outcome was all cause mortality in the 90 days following hospital discharge determined using the US Social Security Administration Death Master File. Adjusted odds ratios were estimated by multivariable logistic regression models with inclusion of covariate terms for age, race, gender, Deyo-Charlson Index, patient type (medical versus surgical), sepsis and number of organs with acute failure.

Results: The cohort patients were 62.6 % male, 21.4 % nonwhite and > 20 kg/m2 in 76.2 %. Mean(SD) MELD score was 15 years. Mean(SD) MELD score was 15 years. Mean(SD) MELD score was 15 years. The exposure of interest was RDW within 24 hours of hospital discharge and categorized a priori as ≤ 13.3 %, 13.3-14.0 %, 14.0-14.7 %, 14.7-15.8 %, 15.8-17.0 % and >17.0 %. The cohort patients were 5 females) patients were identified (group A): 12 rheumatoid arthritis, 2 ankylosing spondylitis, 1 psoriatic arthritis. Oral steroids were used in 6 and methotrexate in 3 patients. The following operations were performed (1 emergency): 8 valve surgery, 5 coronary artery bypass and 2 operations on thoracic aorta. Comparing with the rest of the cohort (group B), the study group patients were older (69.6 ± 7 vs 65.2 ± 10), their average pre-op mean ejection fraction was 57.3 ± 10 % vs 55.6 ± 11 % and their pre-op eGFR (MDRD) was 76.2 ± 23 vs 73.7 ± 23 mL/min/1.73 m2. Pulmonary hypertension-defined as pre-op doppler systolic pulmonary pressure > 30 mmHg was found in 5/15 patients (36.6 % vs 22.49 %, p = 0.34). Median duration of mechanical ventilation was 11 hours for group A vs 7 hours for group B. Transfusion with > 3 red blood units was required in 5/15 (36.6 % vs 23.4 %, p = 0.36). Post-op low cardiac output syndrome developed in 2/15 (13.3 % vs 5.49 %, p = 0.43). Acute kidney injury defined by RIFLE criteria complicated 2/15 patients (13.3 % vs 15.6 %, p = 0.78). Post-op atrial fibrillation developed in 7/15 (46.6 % vs 33.6 %, p = 0.31). One patient required non invasive ventilation for post-op respiratory failure. Median ICU days were 2 in both groups. No patient of the study group developed sternal wound infection or had prolonged (>24 hours) mechanical ventilation while hospital mortality was 0 %.

Conclusions: According to the results of this single-center retrospective study, cardiac surgery procedures could be performed safely in patients with a history of connective tissue disease.

Intensive Care Medicine Experimental 2016, 4(Suppl 1):A768

Introduction: Critically ill patients with body mass index (BMI) lower than 20 kg/m2 have worse outcomes than normal or overweight patients possibly because underweight is a marker of malnutrition. It has been suggested that in malnourished critically ill patients an early increased intake of calories and protein might improve their prognosis.
Objectives: To evaluate the impact of nutritional support, especially calories and protein, on specific outcomes - need of tracheostomy, ICU readmission, and in-hospital mortality - in underweight critically ill patients.

Methods: Prospective, two-center, observational study, was designed to assess the effect of nutritional intake in underweight critically ill patients. All patients consecutively admitted (November 2015 to March 2016) to general intensive care units (ICU) with IMC < 20 kg/m² were included. Exclusion criteria were: palliative care, exclusively oral nutrition, pregnancy, life expectancy < 24 h, and ICU readmission. Patients had their nutritional intake evaluated after ICU admission between days 2 and 3 (1st evaluation). Another evaluation was performed between days 5 and 7 (2nd evaluation) if patient had not been discharged from ICU, was not on exclusively oral nutrition, or on palliative care. Patients were divided into groups according calorie intake (group A: < 20 kcal/kg/day; group B: 20 kcal/kg/day; group C: ≥ 1 g protein/kg/day; group D: ≥ 1 g protein/kg/day). Patients were followed in the hospital until their death or discharge.

Results: The hospital mortality rate of 83 included patients was 55.4% after 17 (10–32) days of follow-up. There was an increment in calories (196 ± 9.7 to 27.6 ± 11.2; p < 0.001) and protein (0.9 ± 0.6 to 1.33 ± 0.7; p < 0.001) intakes between 1st and 2nd evaluation. The caloric intake (Kcal/day) both in the 1st (19.2 ± 9.2 vs. 16.3 ± 10; p = 0.189) and 2nd evaluation (27.8 ± 10 vs. 27.5 ± 11.9; p = 0.0916) did not differ between survivors and non-survivors; there was a trend for a higher protein intake (g/kg/day) in survivors in the 1st evaluation (0.96 ± 0.56 vs. 0.69 ± 0.62; p = 0.051). Mortality did not differ according caloric intake in the 1st (Table 79) and 2nd evaluation. Patients who received > 1 g of protein/day (Group D) in the 1st evaluation (Table 79) had lower mortality than those who received less protein (Group C), but not in 2nd evaluation. Frequency of tracheostomies was higher in patients who received more calories (Group B) and protein (Group D) only in the 1st evaluation. Multivariate logistic models confirmed (OR, 95%CI) that protein intake was negatively associated with mortality [protein intake 0.43(0.18-0.99); SAPS3 1.07(1.02-1.11)] and with need of tracheotomy [protein intake 3.06(1.03-9.07); SAPS3 0.94(0.90-9.99)] even after adjustment for illness severity. ICU readmission did not differ among groups.

Conclusion: In underweight critically ill patients an early high protein intake at ICU admission has a protective role for mortality.

Intensive Care Medicine Experimental 2016, 4(Suppl 1):A769

Introduction: Nutritional risk and malnutrition must be screened at admission in intensive care units (ICU) because these patients usually benefit from early nutritional therapy. Nutritional parameters should be monitored by quality indicators (QI), but their goals and association with patient outcome are still unknown.

Objectives: To estimate the impact of nutritional risk and malnutrition on mortality and new caloric deficit on mortality at a 60 days follow-up in a general ICU population.

Methods: Consecutive adult patients who remained in the ICU for greater than 48 hours were included and prospectively followed. Data were abstracted from electronic health records (EHR) by trained ICU dietitians on their sex, age, APACHE II and baseline nutrition assessment at admission. Daily nutrition information was collected on the type (i.e. EN, PN, oral, none) and amount of nutrition received (total calories) from ICU admission for a maximum of the first 7 days (EN only) unless death or discharge occurred sooner. Heavy caloric deficit occurred when < 25 % of the caloric needs was achieved in the first ICU week. Patients were followed while in hospital and their outcomes determined at 60 days after ICU admission. Online forms were elaborated to enter abstracted data with a secure web-based tool (GoogleDocs, © 2012).

Results
A total of 236 EHR were verify from 2014 to 2015 in 4 this audit, 85.6 % were screened for Nutritional risk of that 91.1 % had nutritional risk according to NRS 2002 tool2, 85.2 % were accessed with ASPEN-ADA3 tool, diagnosing 23.4 % of malnutrition. 91.1 % of the EHR had information on the nutrients received, heavy caloric deficit was verif in 27.4 % of the EHR with this information. Binary logistic regression evidenced risk of mortality at 60 days 8.01 times higher (95%CI 1.86 – 34.7, Wald = 7.8, p = 0.005) in patients malnourished and with heavy caloric deficit in the first ICU week at the same time when compared with patients without these two risk factors (controlled by sex, age and APACHE II). Either malnutrition or heavy caloric deficit when present increases the mortality risk in 5.83 times (95%CI 1.33 – 25.4, Wald = 5.5, p = 0.019). Nutritional risk was not associated with ICU mortality regardless of sex, age and Apache II.

Conclusion: The QI presented are potentially useful nutritional markers and could implement ICU routine, the presence of a dietitian in the multidisciplinary team can facilitate that task. The combination of malnutrition and heavy caloric deficit were relevant nutritional QI associated with ICU mortality regardless of sex, age and Apache II. More studies are needed to establish goals for these QI and to develop this field.
