Search for a new scalar resonance decaying to a pair of Z bosons in proton-proton collisions at $\sqrt{s} = 13$ TeV

The CMS collaboration

E-mail: cms-publication-committee-chair@cern.ch

ABSTRACT: A search for a new scalar resonance decaying to a pair of Z bosons is performed in the mass range from 130 GeV to 3 TeV, and for various width scenarios. The analysis is based on proton-proton collisions recorded by the CMS experiment at the LHC in 2016, corresponding to an integrated luminosity of 35.9 fb$^{-1}$ at a center-of-mass energy of 13 TeV. The Z boson pair decays are reconstructed using the $4\ell$, $2\ell 2q$, and $2\ell 2\nu$ final states, where $\ell = e$ or $\mu$. Both gluon fusion and electroweak production of the scalar resonance are considered, with a free parameter describing their relative cross sections. A dedicated categorization of events, based on the kinematic properties of associated jets, and matrix element techniques are employed for an optimal signal and background separation. A description of the interference between signal and background amplitudes for a resonance of an arbitrary width is included. No significant excess of events with respect to the standard model expectation is observed and limits are set on the product of the cross section for a new scalar boson and the branching fraction for its decay to ZZ for a large range of masses and widths.

https://doi.org/10.1007/JHEP06(2018)127
1 Introduction

The standard model (SM) of particle physics postulates the existence of a single Higgs boson as the manifestation of a scalar field responsible for electroweak (EW) symmetry breaking [1–7]. The ATLAS and CMS Collaborations have discovered a boson with a mass close to 125 GeV [8–10] with properties consistent with those expected for the SM Higgs boson [11–15], and no other fundamental particle that would require explanation beyond the SM (BSM) has been discovered to date. Nonetheless, searches for BSM physics are motivated by a number of phenomena such as the presence of dark matter or baryon...
asymmetry in the universe that are not explained by the SM. Extensions of the SM that attempt to address these questions include two-Higgs-doublet models (2HDM) [16], of which supersymmetry is an example, or other models predicting an extended Higgs-like EW singlet [17]. In the following, we denote the recently discovered scalar boson as $H(125)$. The search for a heavy scalar partner of the $H(125)$, which we will generically denote as $X$, is the subject of this paper.

The $ZZ$ decay has a sizable branching fraction for a SM-like Higgs boson for masses larger than the $Z$ boson pair production threshold, $2m_Z$, and is one of the main discovery channels for masses less than $2m_Z$ [8-10]. Since the mass of a new state $X$ is unknown, the search is performed over a wide range of masses from 130 GeV up to 3 TeV. Three final states are considered: $4\ell$, $2\ell 2q$, and $2\ell 2\nu$, with $\ell = e$ or $\mu$. Previous searches for a new boson decaying to $ZZ$ or $WW$ pairs have been reported by the CMS [18] and ATLAS [19, 20] Collaborations at the CERN LHC, using proton-proton collisions recorded at center-of-mass energies of 7 and 8 TeV, where no significant excess was observed. A data set of proton-proton collisions recorded at a center-of-mass energy of 13 TeV by the CMS experiment in 2016 is used in this analysis, corresponding to an integrated luminosity of $35.9 \, fb^{-1}$.

The approach adopted in this analysis treats a new $X$ boson in a model-independent way. For any given mass $m_X$ of the $X$ boson, both its width $\Gamma_X$ and production mechanism are assumed to be unknown. In this analysis, $m_X$ and $\Gamma_X$ refer to the mass and width of the scalar boson that enter the propagator. No modification from the complex-pole scheme [21, 22] is considered. The two dominant production mechanisms of a scalar boson are gluon fusion (ggF) and EW production, the latter dominated by vector boson fusion (VBF) with a small contribution of production in association with an EW boson $ZH$ or $WH$ (VH). We define the parameter $f_{VBF}$ as the fraction of the EW production cross section with respect to the total cross section. The three parameters $m_X$, $\Gamma_X$, and $f_{VBF}$ are scanned over a wide range of allowed phase space, and limits are set on the $pp \rightarrow X \rightarrow ZZ$ cross section.

The new state $X$ can potentially have a large value $\Gamma_X$: in this case, there is sizable interference between the $X \rightarrow ZZ \rightarrow 4f$ amplitude and that of the SM background process $ZZ/Z\gamma^* \rightarrow 4f$, where $f$ denotes any fermion. The interference distorts both the kinematic distributions and overall yield of the BSM contribution. The SM background includes the contribution from the $H(125) \rightarrow ZZ \rightarrow 4f$ decays, which yields a nonnegligible off-shell contribution above the $2m_Z$ threshold [21]. The above interference effect is present in both ggF and EW processes and is taken into account in this analysis. The reported cross-section limits correspond to the signal-only contribution as it would be in the absence of interference. A novel feature in this analysis is the inclusion of all of the above effects in a parametric way in a likelihood fit to the data. The matrix element (ME) formalism is used both for the parameterization of the likelihood and for the construction of the observables optimal for event categorization.

The paper is organized as follows. In section 2, the CMS detector and event reconstruction techniques are presented. Monte Carlo (MC) simulation of the signal and background processes is described in section 3. Matrix element methods are discussed in section 4. Event selection and categorization in each channel are presented in section 5. Modeling of
the signal distributions and background estimation techniques are described in section 6. Systematic uncertainties are summarized in section 7. In section 8 results are presented, and we conclude in section 9.

2 The CMS detector and event reconstruction

The CMS detector comprises a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter (ECAL), and a brass and scintillator hadron calorimeter (HCAL), each composed of a barrel and two endcap sections, all within a superconducting solenoid of 6 m internal diameter and providing a magnetic field of 3.8 T. Outside of the solenoid are the gas-ionization detectors for muon measurements, which are embedded in the steel flux-return yoke outside the solenoid. The detection layers are made using three technologies: drift tubes, cathode strip chambers, and resistive-plate chambers. Extensive forward calorimetry complements the coverage provided by the barrel and endcap detectors. A more detailed description of the CMS detector, together with a definition of the coordinate system and the relevant kinematic variables used, can be found in ref. [23].

The particle-flow (PF) event algorithm [24] reconstructs and identifies each individual particle with an optimized combination of information from the various elements of the CMS detector. The reconstructed vertex with the largest value of summed physics-object \( p_T \) is taken to be the primary pp interaction vertex. The physics objects are the jets, clustered using the jet finding algorithm [25, 26] with the tracks assigned to the vertex as inputs, and the associated missing transverse momentum, taken as the negative vector sum of the \( p_T \) of those jets. The energy of photons is obtained from the ECAL measurement, corrected for zero-suppression effects. The energy of electrons is determined from a combination of the electron momentum at the primary interaction vertex as determined by the tracker, the energy of the corresponding ECAL cluster, and the energy sum of all bremsstrahlung photons spatially compatible with originating from the electron track. The momentum of muons is obtained from the curvature of the corresponding tracks in the tracker and the muon systems [27]. The energy of charged hadrons is determined from a combination of their momentum measured in the tracker and the matching ECAL and HCAL energy deposits, corrected for zero-suppression effects and for the response function of the calorimeters to hadronic showers. Finally, the energy of neutral hadrons is obtained from the corresponding corrected ECAL and HCAL energy. The missing transverse momentum vector \( \mathbf{p}_T^{\text{miss}} \) is defined as the projection onto the plane perpendicular to the beam axis of the negative vector sum of the momenta of all reconstructed particle-flow objects in an event. Its magnitude is referred to as \( p_T^{\text{miss}} \). The correction mentioned above also applies to the determination of \( p_T^{\text{miss}} \).

Collision events are selected by high-level trigger algorithms [28] that require the presence of leptons passing loose identification and isolation requirements. The main triggers for this analysis select a pair of electrons or muons. Triggers selecting an \( e\mu \) pair are also used for the \( 4\ell \) channel and in control samples for \( 2\ell q \) and \( 2\ell 2\nu \). The minimal \( p_T \) of the leading electron (muon) is 23 (17) GeV, while that of the subleading lepton is 12 (8) GeV. Isolated single-electron (muon) triggers with minimal \( p_T \) of 27 (22) GeV are also employed to complement the double-lepton triggers.
Electrons are measured in the ECAL in the pseudorapidity range $|\eta| < 2.4$. The momentum resolution for electrons with $p_T \approx 45$ GeV from $Z \to ee$ decays ranges from 1.7% for nonshowering electrons in the barrel region to 4.5% for showering electrons in the endcaps [29]. Muons are measured in the range $|\eta| < 2.4$. Muons are reconstructed by combining information from the silicon tracker and the muon system [27]. The matching between the inner and outer tracks proceeds either outside-in, starting from a track in the muon system, or inside-out, starting from a track in the silicon tracker. In the latter case, tracks that match track segments in one or two (out of four) layers of the muon system are also considered in the analysis to collect very low $p_T$ muons that may not have sufficient energy to penetrate the entire muon system. Matching muons to tracks measured in the silicon tracker results in a relative $p_T$ resolution for muons with $20 < p_T < 100$ GeV of 1.3–2.0% in the barrel and better than 6% in the endcaps. The $p_T$ resolution in the barrel is better than 10% for muons with $p_T$ up to 1 TeV [27].

Hadronic jets are clustered from the four-momenta of the particles in a jet reconstructed by the PF algorithm, using the FastJet software package [26]. Jets are clustered using the anti-$k_T$ algorithm [25] with a distance parameter equal either to 0.4 (“AK4 jets”) or 0.8 (“AK8 jets”). Charged PF constituents not associated with the primary vertex are not used in the jet clustering procedure.

Jet energy momentum is determined as the vectorial sum of all particle four-momenta in the jet. Jets are reconstructed in the range $|\eta| < 4.7$. An offset correction is applied to jet energy momenta to account for the contribution from additional proton proton interactions in the same or neighboring bunch crossings (pileup). These corrections are derived from simulation, and are confirmed with in situ measurements of the energy momentum balance in dijet, multijet, $\gamma$ + jet and leptonically decaying $Z +$ jets events [30]. Additional selection criteria are applied to each event to remove spurious jet like features originating from isolated noise patterns in certain HCAL regions.

3 Monte Carlo simulation

Signal events with SM like couplings are generated at next to leading order (NLO) in quantum chromodynamics (QCD) with Powheg 2.0 [31–35] for the ggF and VBF production modes. The decays $X \to ZZ \to 4\ell, 2\ell 2q,$ and $2\ell 2\nu$ are modeled with JHUGen 7.0.2 [36–39], including corrections for the ZZ branching fraction, and correct modeling of the angular correlation among the fermions. A wide range of masses $m_X$ from 100 GeV to 3 TeV is generated with the width $\Gamma_X$ set according to the SM Higgs boson expectation for $m_X$ up to 1 TeV. For higher masses, we choose the width $\Gamma_X = 0.5m_X$, which approximately corresponds to the SM Higgs boson prediction for $m_X = 1$ TeV. The samples are used to derive a generic signal parameterization.

While NLO accuracy in QCD is used in production, no modeling of the interference with background is included at this stage of the simulation. The MELA matrix element package [36–39], based on JHUGen for both $H(125)$ and $X$ signal, and on MCFM 7.0 [40–42] for the continuum background, allows modeling of interference of a broad $X$ resonance with SM background in either ggF or EW production, the latter including VBF and VH processes.
The loop induced production of two Z bosons, \( gg \rightarrow ZZ/\gamma^* \rightarrow 4f \) background, including the off shell tail of the H(125), is modeled at leading order (LO) in QCD with mcfm. The corresponding background from EW production, \( qq'ZZ/\gamma^* \rightarrow 4fqq' \) is modeled at LO in QCD with Phantom 1.2.8 [43]. For both ggF and VBF simulation, the factorization and renormalization scales are chosen as \( m_{ZZ}/2 \), and NNPDF3.0 parton distribution functions (PDFs) [44] are adopted. In order to include higher order QCD corrections to gluon fusion production, LO, NLO, and next to next to leading order (NNLO) signal cross section calculations are performed using the mcfm and hnnlo v2 programs [45–47] for a wide range of masses using the narrow width approximation. The ratio between the NNLO and LO, or between the NLO and LO, is used as a weight depending on the 4f invariant mass (K factor). While this procedure is directly applicable for the signal, it is approximate for the background. However, an NLO calculation is available [48, 49] for the background in the mass range \( 2m_Z < m_{4f} < 2m_t \). There is a good agreement between the NLO K factors calculated for signal and background and any differences set the scale of systematic uncertainties in this procedure, for which we assign a 10% uncertainty. Event yields for the H(125) boson production are normalized to the cross section at NNLO in QCD and NLO in EW for ggF [50] and others taken from ref. [51].

The MELA package is also used to reweight the powheg/JHUGen, mcfm, or Phantom signal samples to model various values of \( m_X \) and \( \Gamma_X \), as well as the interference with the background component.

The background from the production of two Z bosons from quark anti-quark annihilation, \( qq \rightarrow ZZ/\gamma^* \rightarrow 4f \), is evaluated at NLO with powheg [52] and MadGraph5_aMC@NLO 2.3.2 [53]. The WZ production is generated at LO with pythia 8.212 [54], normalized to NNLO in QCD accuracy [55]. The Z + jets (\( Z \rightarrow \ell^+\ell^- \)) simulation is made of a composite sample comprising a set of exclusive LO samples with various associated parton multiplicities, including a dedicated sample with associated b quark production. These samples are produced at LO with MadGraph5_aMC@NLO and corrected to NLO QCD accuracy with a K factor depending on the \( p_T \) of the dilepton pair, derived from MadGraph5_aMC@NLO simulation at NLO with FxFx merging scheme [56]. The simulation of top quark antiquark pair production, \( t\bar{t} \), is performed with powheg at NLO in QCD [57].

All generated samples are interfaced with pythia, configured with the CUETP8M1 tune [58] for simulation of parton showers, hadronization, and underlying event effects. All simulated events are further processed with a Geant4 based description [59] of the CMS detector and reconstructed with the same algorithms as used for data. Supplementary minimum bias (pileup) interactions are added to the simulated events with a multiplicity determined such as to match that observed in data.

### 4 Matrix element techniques

The ME method in this study is utilized in three ways. First, it is used to apply weights to generated events from various models to avoid having to fully simulate the samples, as discussed in section 3. Second, the ME method is used to create a model of a broad
high mass resonance X, including its interference with the SM background, to be used in the likelihood fit. Finally, this method is used to create optimal discriminants for either categorization of events according to likely production mechanism, or to separate signal from the dominant background.

The ME calculations are performed using the MELA package, which provides the full set of processes studied in this paper and uses JHUGen matrix elements for the signal and mcfm matrix elements for the background. The signal includes both the four fermion kinematic properties for the decay $X \rightarrow ZZ \rightarrow 4f$, and the kinematical properties of associated particles in the $X + 2\text{jets}$, VBF, ZH, WH production. The background includes $gg$ or $q\bar{q} \rightarrow ZZ / Z\gamma^* / \gamma^*\gamma^* / Z \rightarrow 4f$ processes, VBF production of a $Z$ boson pair, the associated production of a $Z$ pair with a third vector boson, and the production of a single $Z$ boson in association with jets.

Two of the final states studied in this analysis, $X \rightarrow ZZ \rightarrow 4\ell$ and $2\ell2q$ provide full information about the kinematic properties of the process in both production and decay. This is illustrated in figure 1, where a complete set of angles and invariant masses, denoted as $\Omega$, fully defines the four vectors of all involved particles in the center of mass frame [36, 38]. The overall boost of the system depends on QCD effects beyond LO (in the transverse plane) or PDFs (in the longitudinal direction). Therefore, in these two channels, matrix element calculations are used to create discriminants optimal either for categorization of the production mechanism or to separate signal from background using production and decay information.

The discriminant sensitive to the VBF signal topology with two energetic and forward associated jets is calculated as [18, 60]

$$D_{VBF}^{2\text{jet}} = \left[ 1 + \frac{p_{VBF}(\Omega^{X+JJ}|m_{ZZ})}{p_{XJJ}(\Omega^{X+JJ}|m_{ZZ})} \right]^{-1}, \quad (4.1)$$
where $P_{VBF}$ and $P_{X,jj}$ are probabilities obtained from the JHUGen matrix elements for the VBF and $ggF$ production processes in association with two jets ($X + 2$ jets). This discriminant is equally efficient in separating VBF from either $gg \to X + 2$ jets signal or $gg$ or $q\bar{q} \to 2\ell 2q + 2$ jets background because jet correlations in these processes are distinct from the VBF process. Being independent of the type of fermions produced in the $Z$ boson decay, it is used in both the $X \to ZZ \to 4\ell$ and $X \to ZZ \to 2\ell 2q$ analyses.

In addition, in the $X \to ZZ \to 4\ell$ analysis, the dominant background originates from the $q\bar{q} \to ZZ / Z\gamma^*/\gamma^*\gamma^* \to 4\ell$ process. Therefore, the discriminant sensitive to the $X \to ZZ \to 4\ell$ kinematic properties and optimal for suppression of the dominant background is defined as

$$D_{bkg}^{\text{kin}} = \left[ 1 + \frac{P_{q\bar{q} \to 4\ell}(\Omega_{X \to 4\ell}^j|m_{ZZ})}{P_{X \to 4\ell}(\Omega_{X \to 4\ell}^j|m_{ZZ})} \right]^{-1}. \tag{4.2}$$

In the $X \to ZZ \to 2\ell 2q$ analysis, the dominant background originates from the $Z + 2$ jets process. Therefore, the discriminant sensitive to the $X \to ZZ \to 2\ell 2q$ kinematic properties is calculated as

$$D_{bkg}^{Z_{ij}} = \left[ 1 + \frac{P_{Z_{ij} \to 2\ell 2q}(\Omega_{X \to 2\ell 2q}^j|m_{ZZ})}{P_{X \to 2\ell 2q}(\Omega_{X \to 2\ell 2q}^j|m_{ZZ})} \right]^{-1}. \tag{4.3}$$

In eqs. (4.2) and (4.3), $P_{X \to 4\ell}$ and $P_{X \to 2\ell 2q}$ are the probabilities for the signal, while $P_{q\bar{q} \to 4\ell}$ and $P_{Z_{ij} \to 2\ell 2q}$ are the probabilities for the dominant background processes.

5 Event selection and categorization

The searches in the three final states cover different mass ranges. The $4\ell$ final state has the smallest backgrounds, so the search is performed over the full range from 130 GeV to 3 TeV. The $2\ell 2\nu$ final state suffers from large $Z +$ jets background in the low mass region, and the search range is thus restricted to be between 300 GeV and 3 TeV. For the same reason, the $2\ell 2q$ final state search is performed between 550 GeV and 3 TeV. Event selections are optimized for the search ranges in each final state.

Leptons are reconstructed as described in section 2. Electrons are also required to pass identification criteria based on observables sensitive to the bremsstrahlung along the electron trajectory, the geometrical and momentum energy matching between the electron trajectory and the associated energy cluster in the ECAL, the shape of the electromagnetic shower in the ECAL, and variables that discriminate against electrons originating from photon conversions. Independent selection criteria on such observables are applied in the $2\ell 2\nu$ channel, while a multivariate discriminant based on them is adopted in the $4\ell$ and $2\ell 2q$ channel to retain high efficiency for low $p_T$ leptons. Muons are selected among the reconstructed muon track candidates by applying minimal requirements on the track in both the muon and inner tracker system, and requiring small associated energy deposits in the calorimeters. For muon $p_T$ above 200 GeV, the additional lever arm provided by the outer muon detectors becomes a significant advantage; therefore the charge and momentum
are extracted from the combined trajectory fit for the outside in muons, while otherwise tracks found in the silicon tracker are used.

Electrons and muons with high \( p_T \) are required in the 2\( \ell \)2q (\( >24 \) GeV) and 2\( \ell \)2\( \nu \) (\( >25 \) GeV) final states, while low \( p_T \) (\( >7 \) GeV for electrons and \( >5 \) GeV for muons) leptons are also retained in the 4\( \ell \) final state to ensure high efficiency for masses less than \( 2m_Z \). To suppress nonprompt leptons, the impact parameter in three dimensions of the lepton track, with respect to the primary vertex, is required to be less than 4 times its uncertainty (\( |\text{SIP}_{3D}| < 4 \)).

In addition, an isolation requirement of \( I^\ell < 0.35 \) is imposed to select prompt leptons, where the isolation \( I^\ell \) is defined as

\[
I^\ell \equiv \left( \sum p_T^{\text{charged}} + \max \left[ 0, \sum p_T^{\text{neutral}} + \sum p_T^\gamma - p_T^{\text{PU}}(\ell) \right] \right) / p_T^\ell. \tag{5.1}
\]

The three involved sums run over the \( p_T \) of charged hadrons originating from the primary vertex, of neutral hadrons and of photons in a cone of angular radius \( \Delta R = 0.3 \) around the lepton direction.

Since the isolation variable is particularly sensitive to energy deposits from pileup interactions, a \( p_T^{\text{PU}}(\ell) \) contribution is subtracted, using two different techniques. For muons, we define \( p_T^{\text{PU}}(\mu) \equiv 0.5 \sum_i p_T^{\text{PU},i} \), where \( i \) runs over the momenta of the charged hadron PF candidates not originating from the primary vertex, and the factor of 0.5 accounts for the fraction of neutral particles. For electrons, an area based subtraction technique [26, 61, 62], as implemented in \textsc{FastJet}, is used, in which \( p_T^{\text{PU}}(e) \equiv \rho A_{\text{eff}} \), where the effective area \( A_{\text{eff}} \) is the geometric area of the isolation cone scaled by a factor that accounts for the residual dependence of the average pileup as a function of \( \eta \), and \( \rho \) is the median of the energy density distribution of neutral particles within the area of any jet in the event.

In the 4\( \ell \) and 2\( \ell \)2q final states, an algorithm is used to recover the final state radiation (FSR) from leptons. Photons reconstructed by the PF algorithm within \( |\eta_{\gamma}| < 2.4 \) are considered as FSR candidates if they satisfy \( p_T^\gamma > 2 \) GeV and \( I^\ell < 1.8 \) [63]. Associating every such photon to the closest selected lepton in the event, photons that do not satisfy \( \Delta R(\gamma, \ell)/(p_T^\gamma)^2 < 0.012 \) and \( \Delta R(\gamma, \ell) < 0.5 \) are discarded. The lowest \( \Delta R(\gamma, \ell)/(p_T^\gamma)^2 \) photon candidate for every lepton, if any, is retained. The photons identified as FSR are excluded from any isolation computations.

The momentum scale and resolution for electrons and muons are calibrated in bins of \( p_T^\ell \) and \( \eta^\ell \) using the decay products of known dilepton resonances. The electron momentum scale in data is corrected with a \( Z \rightarrow e\bar{e} \) sample, by adjusting the peak of the reconstructed dielectron mass spectrum to that expected from simulation. A Gaussian smearing is applied to electron energies in simulation such that the \( Z \rightarrow e\bar{e} \) mass resolution agrees with the one observed in data. Muon momenta are calibrated based on a Kalman filter approach [64], using \( J/\psi \) meson and Z boson decays.

A “tag-and-probe” technique [65] based on inclusive samples of Z boson events in data is used to correct the efficiency of the reconstruction and selection for prompt electrons and muons in several bins of \( p_T^\ell \) and \( \eta^\ell \). The difference in the efficiencies measured in simulation and data is used to correct the selection efficiency in the simulated samples.
The jets in the three analyses must satisfy $p_T^{\text{jet}} > 30 \text{ GeV}$ and $|\eta^{\text{jet}}| < 4.7$ and be separated from all selected leptons by $\Delta R(\ell/\gamma, \text{jet}) > 0.4$. The analyses use b tagged jets of $|\eta^{\text{jet}}| < 2.5$ for event categorization and selection, where a b jet is tagged using the combined secondary vertex algorithm [66, 67] based on the impact parameter significance of the tracks associated with the jet, with respect to the primary vertex. The loose working point is used, corresponding to an efficiency of 80% and a mistag rate of 10% for light quark jets.

The main feature distinguishing the two dominant X boson production mechanisms (ggF and VBF) is the presence of associated jets and the kinematic correlation between such jets and the X boson. In order to gain sensitivity to the production process of the X boson, events are split into categories based on such kinematic correlations. In the case of fully reconstructed final states, $X \rightarrow 4\ell$ and $2\ell 2q$, a ME technique is used to categorize events based on the correlation between the two forward jets and the X boson candidate, while in the $2\ell 2\nu$ final state a simpler correlation between the two jets is used.

Subsequent event selections differ depending on the considered final state and are described for each final state in the following.

5.1 $X \rightarrow ZZ \rightarrow 4\ell$

The $X \rightarrow ZZ \rightarrow 4\ell$ analysis uses the same selection as in the measurements of the properties of the H(125) boson in the $H \rightarrow ZZ \rightarrow 4\ell$ decay channel [63]. The Z candidates are formed from pairs of leptons of the same flavor and opposite charge ($e^+e^-, \mu^+\mu^-$) and are required to pass the invariant mass selection $12 < m_{\ell^+\ell^-} < 120 \text{ GeV}$. The flavors of involved leptons define three mutually exclusive channels: $4e$, $4\mu$, and $2e2\mu$. Z candidates are combined into ZZ candidates, wherein we denote as $Z_1$ the Z candidate with an invariant mass closest to the nominal Z boson mass [68], and the other Z candidate $Z_2$. To be considered for the analysis, ZZ candidates have to pass a set of kinematic requirements. The $Z_1$ invariant mass is required to be larger than 40 GeV. All leptons are separated in angular space by at least $\Delta R(\ell_i, \ell_j) > 0.02$. At least two leptons are required to have $p_T > 10 \text{ GeV}$ and at least one is required to have $p_T > 20 \text{ GeV}$. In the $4\mu$ and $4e$ channels, where an alternative $Z_aZ_b$ candidate can be built out of the same four leptons, candidates with $m_{Z_b} < 12 \text{ GeV}$ are removed if $Z_a$ is closer to the nominal Z boson mass than $Z_1$ is.

In ref. [63], six categories are defined based on the number and types of particles associated with the H(125) boson. Here we follow the same approach with some optimization specific for a high mass search. Two categories dedicated to the production mechanisms are used: VBF jets and inclusive; to further improve the efficiency in the electron channels at high $p_T$, a relaxed selection electron (RSE) category is added. The $|\text{SIP}_{3D}| < 4$ requirement in the standard electron selection removes fake electrons from photon conversions, which are not dominant at high masses. The requirement becomes the main cause of efficiency losses at high $p_T$. The second cause of the efficiency loss, particularly at high masses, is the opposite sign lepton charge requirement, as the charge misidentification rate increases with lepton $p_T$. Thus, a relaxed selection removing both requirements on at most one pair of electrons is applied for $m_{4\ell} > 300 \text{ GeV}$. The detailed categorization is structured as follows:
As a result of the above categorization, events are split into eight categories: 4e, 4\(\mu\), 2e2\(\mu\), in either the VBF-tagged or the untagged category, or 4e and 2e2\(\mu\) in the RSE category. Each event is characterized by two observables (\(m_{4\ell}\) and \(D_{2\text{jet}}^{\text{VBF}}\)) that are shown in figure 2 and figure 3, together with several signal hypotheses.

5.2 \(X \rightarrow ZZ \rightarrow 2\ell 2q\)

In the \(X \rightarrow ZZ \rightarrow 2\ell 2q\) analysis, events are selected by combining leptonically and hadronically decaying Z candidates. The lepton pair selection is similar to the four-lepton analysis:
pairs of opposite sign and same flavor electrons or muons with invariant mass between 60 and 120 GeV are constructed. A $p_T > 40$ GeV requirement is applied on at least one of the leptons in the pair, and a minimum dilepton $p_T$ of 100 GeV is imposed to reject Drell-Yan events with small hadronic recoil.

Hadronically decaying Z boson candidates ($Z_{\text{had}}$) are reconstructed using two distinct techniques, which are referred to as “resolved” and “merged” in the following. In the resolved case, the two quarks from the Z boson decay form two distinguishable AK4 jets, while in the merged case a single AK8 jet with a large $p_T$ is taken as a $Z_{\text{had}}$.

In the merged jet case, a pruning algorithm is applied to the AK8 jet \cite{69, 70}. The goal of the algorithm is to recluster the jet constituents, while applying additional requirements that eliminate soft, large angle QCD radiation that artificially increases the jet mass relative to the nominal Z boson mass. We adopt the unified nomenclature $m(Z_{\text{had}})$ to refer to the hadronically decaying Z candidate mass, corresponding to the dijet invariant mass in the resolved case and the jet pruned mass in the merged case. The reconstructed $Z_{\text{had}}$ is required to have an invariant mass around the Z boson mass: 40 < $m(Z_{\text{had}})$ < 180 GeV and $p_T > 100$ (170) GeV in the resolved (merged) case. Merged jets must also be separated from all selected leptons by $R(\ell; \text{jet}) > 0.8$. In addition, in the merged jet selection we exploit substructure techniques commonly used in searches including Lorentz boosted bosons in the final state \cite{71}. The $N$-subjettiness $\tau_N$ is defined as

$$\tau_N = \frac{1}{d_0} \sum_k p_{T,k} \min(\Delta R_{1,k}, \Delta R_{2,k}, \ldots, \Delta R_{N,k}),$$

where the index $k$ runs over the jet constituents and the distances $\Delta R_{N,k}$ are calculated with respect to the axis of the $n$th subjet. The normalization factor $d_0$ is calculated as $d_0 = \sum_k p_{T,k} R_0$, setting $R_0$ to the jet radius of the original jet. Jets with smaller $\tau_N$ are more compatible with the $N$-subjets configuration. We use the ratio of 2-subjettiness over 1-subjettiness, $\tau_{21} = \tau_2 / \tau_1$, as the discriminating variable for the jet substructure and impose a $\tau_{21} < 0.6$ requirement on merged $Z_{\text{had}}$ candidates.

---

Figure 3. Distributions of $D_{\text{bkg}}^{\text{kin}}$ for all selected events. Signal expectations including the interference effect for several mass and width hypotheses are shown. The signals are normalized to a total of 400 events.
Events that pass the above selection and additionally have $m(Z_{\text{had}})$ in the range $[70, 105]$ GeV form the signal region, covering 1–2 standard deviations dijet mass resolution. On the other hand, events that have $m(Z_{\text{had}})$ in the range $[40, 70]$ GeV or $[135, 180]$ GeV form the sideband regions and are retained for background estimation.

An arbitration procedure is used to rank multiple $Z_{\text{had}}$ candidates reconstructed in a single event: merged candidates have precedence over resolved candidates if they have $p_T > 300$ GeV and the accompanying leptonically decaying $Z$ candidate has $p_T(\ell^+\ell^-) > 200$ GeV; resolved candidates have precedence otherwise. Within each selection category the candidate with the largest $p_T$ has priority over the others.

The hadronically and leptonically decaying $Z$ boson candidates are combined to form a resonance candidate. In order to improve the $ZZ$ invariant mass resolution in the resolved jet case, a kinematic fit is performed using a mass constraint on the intermediate decay $Z \rightarrow q\bar{q}$. The constraint improves the signal resolution by 7–10%. When a candidate belongs to the signal region, we reevaluate the kinematical distributions of final state particles (here the $p_T$ of the two jets forming the $Z$ boson of the resonance candidate) with a constraint on the reconstructed $Z$ boson mass to follow the $Z$ boson line shape. For each event, the likelihood is maximized and the $p_T$ of the jets is updated. After refit, the mass of the $Z$ boson candidate and $m_{ZZ}$ are recalculated. This procedure is not applied to events in the sidebands, where $m(Z_{\text{had}})$ is very different from the nominal $Z$ boson mass.

The reconstructed $ZZ$ candidate mass $m_{ZZ}$ denotes the dilepton + dijet mass $m_{\ell\ell jj}$ in the resolved case and the dilepton + merged jet invariant mass $m_{\ell\ell jj}$ in the merged case. A requirement of $m_{ZZ} > 500$ GeV is imposed to reduce the $Z + \text{jets}$ background.

To increase the sensitivity to the different production modes, events are categorized into VBF and inclusive types. Furthermore, since a large fraction of signal events is enriched with b quark jets due to the presence of $Z \rightarrow b\bar{b}$ decays, a dedicated category is defined. The definitions are as follows:

- **VBF-tagged** requires two additional and forward jets besides those constituting the hadronic $Z$ boson candidate; a mass dependent selection criterion on $D_{2\text{jet}}^{VBF}$ is applied;
- **b tagged** consists of the remaining events with two b tagged jets (in the resolved case) or two b tagged subjets from the hadronic $Z$ boson candidate;
- **Untagged** consists of the remaining events.

As a result of this categorization, events are split into twelve categories: 2e2q or 2\mu2q, either VBF-tagged, b-tagged, or untagged, and each with either merged jets or resolved jets. Each event is characterized by the two observables $(m_{\ell\ell}, D_{bkg}^{\ell\ell jj})$. Figure 4 shows the invariant mass distribution for merged and resolved events in each category after the selection. Figure 5 shows the $D_{bkg}^{\ell\ell jj}$ and $D_{2\text{jet}}^{VBF}$ distributions for resolved events in each category together after the selection.

### 5.3 $X \rightarrow ZZ \rightarrow 2\ell 2\nu$

In the $X \rightarrow ZZ \rightarrow 2\ell 2\nu$ channel, events are selected by combining dilepton $Z$ boson candidates with relatively large $p_T^{\text{miss}}$. Events are selected requiring two leptons of the same
Figure 4. Distributions of the invariant mass $m_{\text{ZZ}}$ in the signal region for the merged (left) and resolved (right) case for the different categories in the $2l2q$ channel. The points represent the data, the stacked histograms the expected backgrounds from simulation, and the open histograms the expected signal. The blue hatched bands refer to the sum of background estimates derived from either simulation or control samples in data, as described in the text. Lower panels show the ratio between data and background estimation in each case.

Flavor that have an invariant mass within a 30 GeV window centered on the nominal Z boson mass. For X boson masses considered in this analysis ($>300$ GeV), the Z bosons from the X boson decay are typically produced with a large $p_T$. To suppress the bulk of the Z + jets background, the $p_T$ of the dilepton system is therefore required to be greater than 55 GeV, and a $p_T^{\text{miss}}$ threshold of 125 GeV is imposed. The region of large $p_T^{\text{miss}}$ is contaminated by Z + jets events in which the $p_T^{\text{miss}}$ is largely due to mismeasurements of
the jet energies. To suppress this contribution, events are removed if the azimuthal angle between the $p_T^{\text{miss}}$ and the closest jet with $p_T > 30$ GeV is smaller than 0.5 radians. An additional selection requirement $|\Delta\phi(Z, p_T^{\text{miss}})| > 0.5$ is placed in order to remove events for which the instrumental $p_T^{\text{miss}}$ is not well controlled.

Top quark decays are often associated with the production of leptons and missing transverse momentum in the final state but are also characterized by the presence of jets originating from b quarks (b jets). The top quark background is suppressed by applying a veto on events having a b tagged jet with $p_T > 30$ GeV. To reduce the WZ background in which both bosons decay leptonically, any event with an additional $e$ ($\mu$) passing loose identification and isolation criteria with $p_T > 10$ (3) GeV is rejected.

We select events with $p_T^{\text{miss}} \geq 125$ GeV and fit the transverse mass $m_T$ distribution for the selected events. The $p_T^{\text{miss}}$ requirement rejects background processes that could lead to high $m_T$ because of the kinematic properties of the dilepton pair in the event. The $p_T^{\text{miss}}$ criterion is optimized based on expected signal significance. The significance is found to be quite stable with the chosen $p_T^{\text{miss}}$ requirement for masses above 400 GeV.

The transverse mass is reconstructed from the dilepton and $p_T^{\text{miss}}$ system via the following definition:

$$m_T^2 = \left( \sqrt{p_T(\ell\ell)^2 + m(\ell\ell)^2} + \sqrt{p_T^{\text{miss}} + m_Z^2} \right)^2 - (\vec{p}_T(\ell\ell) + p_T^{\text{miss}})^2,$$

where $\vec{p}_T(\ell\ell)$ and $m(\ell\ell)$ are the transverse momentum and invariant mass of the dilepton system, respectively. In order to maximize the sensitivity, the search is carried out in different jet multiplicity categories defined as follows:

- **VBF-tagged**: in this category we require two or more jets in the forward region with a pseudorapidity gap ($|\Delta\eta|$) between the two leading jets greater than 4, and a minimal invariant mass of those two jets of 500 GeV. The two leptons forming the Z boson candidate are required to lie between these two jets in $\eta$, while no other jets ($p_T > 30$ GeV) are allowed in this central region;
• ≥ 1-jet: events with at least one reconstructed jet with \( p_T > 30 \text{ GeV} \), but failing the VBF selection;

• 0-jet: events without any reconstructed jet with \( p_T > 30 \text{ GeV} \).

The last two categories are the most sensitive to the signal produced via ggF but have different expected signal to background ratios. As a result of the above selection, events are split into six categories: 2e2\( \nu \) or 2\( \mu \)2\( \nu \), either 0-jet, ≥ 1-jet or VBF-tagged. Figure 6 shows the \( m_T \) distributions for the signal and background processes superimposed, in the six event categories.

6 Signal and background parameterization

The goal of the analysis is to determine if a set of X boson parameters \( m_X, \Gamma_X \), and \( \sigma_i \mathcal{B}_X \rightarrow ZZ \) is consistent with the data, where \( \sigma_i \mathcal{B}_X \rightarrow ZZ \) is the product of the signal production cross section and the \( X \rightarrow ZZ \) branching fraction in each production channel \( i \) (gluon fusion or EW production). In practice, the \( \sigma_i \mathcal{B} \) for \( i = 1,2 \) are expressed in terms of \( \sigma_{tot} \mathcal{B}_X \rightarrow ZZ \) and \( f_{VBF} \), where \( \sigma_{tot} \) is the sum of the cross sections in the two production channels. The confidence intervals on \( \sigma_{tot} \mathcal{B}_X \rightarrow ZZ \) are determined from profile likelihood scans for a given set of parameters \( (m_X, \Gamma_X, f_{VBF}) \). The extended likelihood function is defined for candidate events as

\[
\mathcal{L} = \exp \left( -\sum_i n_{i,vv}^i - \sum_i n_{i,bkg}^i \right) \prod_k \left( \sum_i n_{i,vv}^i \mathcal{P}_{i,vv}^i(\vec{x}_j; m_X, \Gamma_X) + \sum_i n_{i,bkg}^i \mathcal{P}_{i,bkg}^i(\vec{x}_j) \right),
\]

where \( n_{i,vv}^i \) and \( n_{i,bkg}^i \) are the numbers of signal and background events in channel \( i \). The observables \( \vec{x}_j \) are defined for each event \( j \) in category \( k \) as discussed in sections 5.1, 5.2, and 5.3. There are several signal and background types \( i \), defined for each production mechanism. The background processes that do not interfere with the signal are described by the probability density functions (pdfs) \( \mathcal{P}_{i,bkg}^i(\vec{x}_j) \). The \( vv \rightarrow 4f \) process is described by the pdf \( \mathcal{P}_{i,vv}^i(\vec{x}_j; m_X, \Gamma_X) \) for \( vv = gg \) (gluon fusion) and \( vv = VV \) (EW production). This pdf describes the production and decay of the X boson signal, SM background, including H(125), and interference between all these contributions and is parameterized as follows:

\[
\mathcal{P}_{i,vv}^i(\vec{x}_j; m_X, \Gamma_X) = \mu_i \mathcal{P}_{i,vv}^{i,k}(\vec{x}_j; m_X, \Gamma_X) + \sqrt{\mu_i} \mathcal{P}_{\text{int}}^{i,k}(\vec{x}_j; m_X, \Gamma_X) + \mathcal{P}_{i,vv}^{i,k}(\vec{x}_j), \]

where \( \mu_i \) is the relative signal strength for production type \( i \) defined as the ratio of \( \sigma_i \mathcal{B} \) with respect to a reference value, for which normalization of the pdf is determined. The interference contribution \( \mathcal{P}_{\text{int}}^{i,k} \) scales as \( \sqrt{\mu_i} \) and the pure signal as \( \mu_i \), while both depend on the signal parameters \( m_X \) and \( \Gamma_X \). The likelihood defined in eq. (6.1) is maximized with respect to the nuisance parameters, which include the constrained parameters describing the systematic uncertainties.

6.1 Signal model

The parameterization of \( \mathcal{P}_{i,vv}^{i,k}(\vec{x}_j; m_X, \Gamma_X) \) is performed using the MC simulation discussed in section 3 with the ME method. In the case of the \( X \rightarrow ZZ \rightarrow 4\ell \) or 2\( \ell \)2\( q \) channels,
Figure 6. Distributions of the transverse mass $m_T$ in the signal region for the different analysis categories for the $2\ell 2\nu$ channel, in the $ee$ (left) and $\mu\mu$ final states (right). The points represent the data and the stacked histograms the expected background. The open histograms show the expected gluon fusion and VBF signals for the product of cross section and branching fraction equal to $\sigma(pp \to H \to ZZ) = 50$ fb. Lower panels show the ratio of data to the expected background. The shaded areas show the systematic and total combined statistical and systematic uncertainties in the background estimation.

a full reconstruction of the final state is possible. Therefore, the ideal differential distribution prior to detector effects $P_{\nu\nu}^{\text{ideal}}$, equivalent to eq. (6.2), is parameterized using ME techniques and is further corrected for detector acceptance and resolution effects. In the case of $X \to ZZ \to 2\ell 2\nu$, this approach is not possible because of missing neutrinos: MC simulation is reweighted for each hypothesis of $m_X$, $\Gamma_X$, and $\sigma_iB_{X \to ZZ}$, leading to template
parameterization of $P_{ij}^{k}$ for each set of signal parameters. While ultimately the two approaches are equivalent, the former approach is more flexible in implementation, and the latter avoids the intermediate step of ideal pdf parameterization.

In the $X \rightarrow ZZ \rightarrow 4\ell$ or $2\ell 2q$ channels, we parameterize the signal mass shape as follows. A pdf after detector effects $M_{ij}^{\text{reco}}(m_{ZZ})$ is implemented with the multiplicative efficiency function $\mathcal{E}(m_{ZZ})$ and convolved with a mass resolution function $\mathcal{R}(m_{ZZ}|m_{ZZ}^{\text{Gen}})$, both extracted from simulation of the ggF and VBF processes:

$$M_{ij}^{\text{reco}}(m_{ZZ}) = (\mathcal{E}(m_{ZZ}^{\text{Gen}}), M_{ij}(m_{ZZ}^{\text{Gen}}|m_{X}, \Gamma_{X})) \otimes \mathcal{R}(m_{ZZ}|m_{ZZ}^{\text{Gen}}). \quad (6.3)$$

The parameterizations of $\mathcal{R}(m_{ZZ}|m_{ZZ}^{\text{Gen}})$ and $\mathcal{E}(m_{ZZ}^{\text{Gen}})$ cover the mass range from 100 GeV to 3.5 TeV. Figure 7 shows the efficiencies in the $X \rightarrow 4\ell$ and $X \rightarrow 2\ell 2q$ channels in the various categories. The resolution in the $4\ell$ final state is 1–2% and 3–5% in the $2\ell 2q$ final state. With the above ingredients, the $m_{ZZ}$ parameterization is shown in figure 8, for a boson with $m_{X} = 450$ GeV, $\Gamma_{X} = 10$ GeV decaying to four leptons. The interference contributions from H(125) and gg → ZZ background are also shown.

The 2D signal distributions in the $4\ell$ and $2\ell 2q$ final states are built with the conditional template $T(D_{\text{bkg}}|m_{ZZ})$, which describes the $D_{\text{bkg}}$ discriminant distribution from eq. (4.2) or (4.3) for each value of $m_{ZZ}$:

$$P_{ij}^{k}(m_{ZZ}, D_{\text{bkg}}) = M_{ij}^{\text{reco}}(m_{ZZ})T(D_{\text{bkg}}|m_{ZZ}). \quad (6.4)$$
Figure 8. Parameterizations of the four lepton invariant mass for ggF (left) and VBF (right) production modes, for $m_X = 450\text{ GeV}$, $\Gamma_X = 10\text{ GeV}$. The interference contributions from $H(125)$ and $gg \rightarrow ZZ$ or $VV \rightarrow ZZ$ are also shown. The signal cross section used corresponds to the limit obtained in the 4$\ell$ final state.

The template $\mathcal{T}(D_{\text{bkg}}|m_{ZZ})$ parameterization includes all detector effects affecting the $D_{\text{bkg}}$ distribution. A closure of the full model described by eq. (6.4) is achieved by comparing the model to the simulation for a number of signal parameters.

6.2 Background model

Common backgrounds among the three final states include the $gg(VV) \rightarrow ZZ$ process, $ZZ$ produced via $q\bar{q}$ annihilation, as well as the $WZ$ production process. The $ggF$ and EW production of the $gg(VV) \rightarrow ZZ$ background are treated together with the $X$ boson signal and background, including interference between the corresponding amplitudes, as discussed in detail in section 6.1. Higher order corrections are applied to these processes as discussed in section 3.

The production of $ZZ$ via $q\bar{q}$ annihilation is estimated using simulation. The fully differential cross section for the $q\bar{q} \rightarrow ZZ$ process is computed at NNLO [72], and the NNLO/NLO K factor as a function of $m_{ZZ}$ is applied to the POWHEG sample. This K factor varies from 1.0 to 1.2 and is 1.1 at $m_{ZZ} = 125\text{ GeV}$. Additional NLO EW corrections, which depend on the flavor of the initial state quarks and on kinematic properties, are also applied in the region $m_{ZZ} > 2m_Z$, where the corrections are computed [73-75]. The $WZ$ production is estimated using simulation, where photon induced EW corrections are applied [76, 77].

The analysis specific background processes, or the ones whose contribution is derived from control samples in data, are discussed in the following sections.

6.2.1 $X \rightarrow ZZ \rightarrow 4\ell$

The most important background to the $X$ signal in the 4$\ell$ channel, in addition to the irreducible $ZZ$ arises from processes in which decays of heavy flavor hadrons, in flight decays of
light mesons within jets, or photon conversion or decay of charged hadrons overlapping with \( \pi^0 \) decays are misidentified as leptons. The main processes producing these backgrounds are \( Z + jets \), \( t\bar{t} + jets \), \( Z\gamma + jets \), \( WW + jets \), and \( WZ + jets \) production. Collectively, we denote these as “reducible” backgrounds. The contribution from the reducible background is estimated using two independent methods based on data from dedicated control regions. The control regions are defined by a dilepton pair satisfying all the requirements of a \( Z_1 \) candidate and two additional leptons, opposite sign (OS) or same sign (SS), satisfying more relaxed identification criteria than the ones used for the selection and categorization for the signal events. These four leptons are then required to pass the analysis ZZ candidate selection. The event yield in the signal region is obtained by weighting the control region events by the lepton misidentification probability, defined as the fraction of non signal leptons that are identified by the analysis selection criteria.

The lepton misidentification probabilities are measured separately for electrons and muons from a control sample that requires a \( Z_1 \) candidate consisting of a pair of leptons, both passing the selection requirements used in the analysis, and exactly one additional lepton passing the relaxed selection.

The predicted yield in the signal region of the reducible background is the result of a combination of the two methods described above. The shape of the \( m_{4\ell} \) distribution for the reducible background is obtained by combining the prediction from the OS and SS methods and fitting the distributions with empirical functional forms built from Landau [78] and exponential distributions.

6.2.2 \( X \rightarrow ZZ \rightarrow 2\ell 2q \)

The majority of the background (>90%) is composed of events from \( Z + jets \) production, where jets associated to the Drell-Yan production are misidentified as coming from a hadronic \( Z \) decay. Subdominant backgrounds comprise events from \( t\bar{t} \) production and from diboson EW production.

The \( t\bar{t} \) background is an important source of contamination in the b tagged category. It is estimated from data using \( e^\pm \mu^\mp \) events passing the same selection as for the signal. This method accounts for other small backgrounds (such as \( WW + jets \), \( Z \rightarrow \tau^+\tau^- + jets \), and single top quark production) where the lepton flavor symmetry can be used as well. Because of the limited number of events in the \( e^\pm \mu^\mp \) control region, the \( m_{ZZ} \) shapes are taken from \( t\bar{t} \) simulation, and the statistical uncertainty in the control region is considered as the uncertainty in the background estimation.

In the \( Z+ \) jets background, the misidentified hadronic \( Z \) comes either from the combinatoric background of \( Z + 2 \) jets events where the dijet system happens to have an invariant mass in the range compatible with that of the \( Z \) boson (resolved category) or from an unusual parton shower and hadronization development for a single jet, leading to a configuration similar to that of the boosted \( Z \rightarrow q\bar{q} \) decay (merged category). In both cases, and in each analysis category, a sideband region with a misidentified hadronic \( Z \) mass close to that of the signal region can be used to estimate the contribution of this background. To address the correlation between the hadronic \( Z \) mass and \( m_{ZZ} \) in these configurations, a correction factor is estimated from simulation.
The alpha transfer factor $\alpha(m_{ZZ})$, defined as

$$\alpha(m_{ZZ}) = \frac{\Lambda_{\text{MC}}^{\text{SIG}}(m_{ZZ})}{\Lambda_{\text{SB}}^{\text{MC}}(m_{ZZ})},$$

is calculated as the ratio of the $m_{ZZ}$ distributions in the signal and sideband regions for $Z+$jets simulated events. The alpha function is multiplied by the sideband $m_{ZZ}$ distribution to derive the $Z+$jets contribution in the signal region. The $Z+$jets distribution from the sideband is obtained by subtracting the subdominant backgrounds from MC prediction. Both the shape and the yield for the $Z+$jets background are estimated using this method.

While a binned evaluation of the product of the alpha factor and the sideband yields would be a complete estimate of the background, low event yields from data or simulation in specific bins or event categories could induce large statistical fluctuations in the bins with smaller event yields, occurring at large values of $m_{ZZ}$. We define a “transition” mass value $\tilde{m}_{ZZ}$. For $m_{ZZ} < \tilde{m}_{ZZ}$, the binned evaluation is used as mentioned above. For $m_{ZZ} > \tilde{m}_{ZZ}$, in order to smooth the background estimation, the $Z+$jets shape is then fit using a sum of two exponential functions (a single exponential function) for the resolved jet untagged category (the remaining categories). A binned estimation for $m_{ZZ} > \tilde{m}_{ZZ}$ is then obtained by integrating the smoothed estimation in the corresponding intervals. The statistical uncertainty derived from the fit is propagated to the final result using the full covariance matrix.

6.2.3 $X \rightarrow ZZ \rightarrow 2\ell 2\nu$

The $Z+$jets background is modeled from a control sample of events with a single photon produced in association with jets ($\gamma+$jets). This choice has the advantage of making use of a large sample, which captures the source of instrumental $p_T^{\text{miss}}$ from the $Z$ production in all important aspects, i.e. production mechanism, underlying event conditions, pileup scenario, and hadronic recoil. By using the $\gamma+$jets expectation we avoid the need to use the prediction from simulation for the instrumental background arising from the mismeasurement of jets. Each $\gamma+$jets event must fulfill similar requirements as the dilepton events: no b tagged jets, no additional identified leptons, and a significant transverse momentum ($p_T \geq 55$ GeV).

The kinematic properties and overall normalization of $\gamma+$jets events are matched to $Z+$jets in data through an event by event reweighting as a function of the boson $p_T$ in each of the event categories separately, to account for the dependence of the $p_T^{\text{miss}}$ on the associated hadronic activity. Contamination of the photon data by processes that lead to a photon produced in association with genuine $p_T^{\text{miss}}$, such as $W(\ell\nu) + \gamma$ and $W(\ell\nu) +$ jets where the jet is mismeasured as a photon, and $Z(\nu\nu) + \gamma$ events, are subtracted using simulation. The simulation of the $p_T^{\text{miss}}$ in such events is more reliable than in $Z+$jets as the $p_T^{\text{miss}}$ is induced by a neutrino and not by detector features. After the $p_T$ reweighting and the $p_T^{\text{miss}}$ requirement, these events represent less than 25% of the photon sample. This procedure yields a good description of the $p_T^{\text{miss}}$ distribution in $Z+$jets events, as shown in figure 9, which compares the $p_T^{\text{miss}}$ distribution of the reweighted $\gamma+$jets events along with other backgrounds to the $p_T^{\text{miss}}$ distribution of the dilepton events in data.
Figure 9. Distribution of the missing transverse energy $p_T^{\text{miss}}$ in the dilepton signal region. The points represent the data and the stacked histograms the expected backgrounds. The lower panel shows the ratio between data and background estimation.

To compute $m_T$ for each $\gamma + \text{jets}$ event, $p_T^{\text{miss}}(\ell\ell)$ is defined as the photon $p_T^{\text{miss}}$ and the value of $m(\ell\ell)$ is chosen according to a probability density function constructed from the measured dilepton invariant mass distribution in data (dominated by $Z + \text{jets}$ events). The uncertainty in this background estimate includes a statistical contribution from the photon control sample and a contribution from the simulations used to subtract processes with photon and genuine $p_T^{\text{miss}}$, and is found to be equal to 100% in the signal region. Another 10% contribution comes from the degree of agreement between the $\gamma + \text{jets}$ prediction and the $p_T^{\text{miss}}$ distributions in a simulated dilepton sample. Uncertainties in the production cross section of the subtracted processes with genuine $p_T^{\text{miss}}$ are also accounted for and are on the order of 25%.

The background processes that do not involve a $Z$ resonance (nonresonant background) are estimated using a control sample of events with dileptons of different flavor ($e^e^-, \mu^\mu^-, e^\mu, \mu^e$) that pass the analysis selection. This background consists mainly of leptonic $W$ decays from $t\bar{t}$, $tW$, and $WW$ events. Small contributions from single top quark events produced in $s$- and $t$-channels, $W + \text{jets}$ events in which the $W$ boson decays leptonically and a jet is mismeasured as a lepton, and $ZZ$ or $Z$ events where a $Z$ decays into $\tau$ leptons, which produce light leptons and $p_T^{\text{miss}}$, are also included in this estimate. This method cannot distinguish between the nonresonant background and the contribution from $H \rightarrow WW \rightarrow 2\ell 2\nu$ events, which is treated as a part of the nonresonant background estimate. The numbers of nonresonant background events $N_{\mu\mu}$ and $N_{ee}$ in the $e^e^-$ and $\mu^\mu^-$ final states are estimated by correcting the number of selected events $N_{e\mu}$ in the $e^\mu^-\mu^+$ final state. The correction factor accounts for the difference in branching fractions, acceptance and efficiency between unlike flavor and same flavor dilepton events, and is computed as:

$$N_{\mu\mu} = \frac{N_{\mu\mu}^{\text{SB}}}{N_{e\mu}^{\text{SB}}} N_{e\mu}, \quad N_{ee} = \frac{N_{ee}^{\text{SB}}}{N_{e\mu}^{\text{SB}}} N_{e\mu},$$

where $N_{ee}^{\text{SB}}$, $N_{\mu\mu}^{\text{SB}}$, and $N_{e\mu}^{\text{SB}}$ are the numbers of events in a sideband control sample of $e^e^-$, $\mu^\mu^-$, and $e^\mu^-\mu^+$ final states, respectively. The sideband selection is defined by $40 < m(\ell\ell) < 70 \text{ GeV}$ or $110 < m(\ell\ell) < 200 \text{ GeV}$, $p_T^{\text{miss}} > 70 \text{ GeV}$, and at least one $b$ tagged
jet. The requirement of a b tagged jet is used to provide a sample enriched in top quark events and to suppress possible contamination from Z+jet events where a jet is misidentified as a lepton. The correction factor measured in the sideband is 0.37 ± 0.01 (stat) and 0.68 ± 0.01 (stat) for the ee and μμ channels, respectively. The uncertainty in the estimate of the nonresonant background is determined via MC closure tests using simulated events as well as by comparing results calculated from sideband regions. The total error is within 13%, which is assigned as the systematic uncertainty in this method.

7 Systematic uncertainties

The three final states share common systematic uncertainties arising from the theoretical prediction, reconstructed objects, and common backgrounds. Theoretical uncertainties that affect both the signal and background estimation include uncertainties from the renormalization and factorization scales and the choice of the PDF set. The uncertainties from the renormalization and factorization scale are determined by varying these scales independently by factors of 0.5 and 2 with respect to their nominal values, while keeping their ratio between 0.5 and 2. The uncertainties from the PDFs are obtained from the root mean squares of the variations, using different replicas of the default NNPDF set. An uncertainty of 10% in the K factor used for the gg → ZZ prediction is applied, which is derived from renormalization and factorization scale variations. The uncertainty in the NNLO-to-NLO K factor for the ZZ and WZ cross sections is about 10%. The renormalization and factorization scale and PDF uncertainties are applied to the event categorization and overall signal and background yields. A systematic uncertainty of 2% in the Z boson branching fraction value is taken into account for the signal yields [51].

The uncertainty in the knowledge of the integrated luminosity of the data samples (2.5%) introduces an uncertainty in the numbers of signal and background events passing the final selection. Uncertainties in the lepton identification and reconstruction efficiencies lead to 2.5% uncertainties in the 4μ and 9% in the 4e final states for the 4ℓ selection, 4–8% (2e and 2μ) for 2e2q and 6–8% for 2μ2ν in the normalizations of both signal and background. The uncertainties in the lepton energy scales are 0.01–0.1% for muons and 0.3% for electrons. A 20% relative uncertainty in the signal resolution is assigned due to per lepton energy resolution in the 4ℓ and 2e2q final states. The jet energy scale (JES), jet energy resolution (JER) and jet reconstruction efficiency uncertainties affect both signal and background yields and represent the most important uncertainties for the 2ℓ2q signal shapes. The systematic uncertainties that are common among the three final states are summarized in table 1.

In addition, each final state has channel specific uncertainties, mainly from the background estimations based on control samples in data, as well as from merged jet reconstruction.

7.1 X → ZZ → 4ℓ

Experimental uncertainties for this channel arise mainly from the reducible background estimation. Impacts from the limited numbers of events in the control regions as well as in
Table 1. Sources of uncertainties considered in each of the channels included in this analysis. Uncertainties are given in percent. The numbers shown as ranges represent the uncertainties in different final states or categories. Most uncertainties affect the normalizations of the background estimations or simulated event yields, and those that affect the shape of kinematic distributions as well are labeled with (*).

</table>

The dominant uncertainties in the signal selection efficiency for this channel arise from uncertainties in the efficiencies to tag the hadronic jet as a $Z$ in the high mass boosted categories, and from uncertainties in the $b$ tagging efficiency. The efficiency of the boosted boson tagging selection and its corresponding systematic uncertainty are measured from data using a sample enriched in $t\bar{t}$ events. Uncertainties in the signal efficiencies from the jet mass scale and resolution are 1–9% and 7–13% depending on the mass. $\tau_{31}$ selection scale factor and extrapolation lead to 8% and 2–8% uncertainties. The $b$ tagging efficiencies and their corresponding systematic uncertainties are measured from data enriched in $t\bar{t}$ events. They account for 5–7% uncertainties in the total signal efficiencies.
For the background estimated from data, the statistical uncertainty of the $e^\pm \mu^\pm$ control sample is propagated to an uncertainty in the $t\bar{t}$+WW estimation. The alpha method for the $Z +$ jets background estimation depends on the uncertainty in the extrapolation factor and on the amount of data of the dijet mass or pruned jet mass sideband region. Jet energy scale and resolution affect the extrapolation factor $\alpha(m_{ZZ})$ by 3–10% depending on the mass. In the low mass region, the statistical uncertainties in the simulated samples and mass sidebands in data are propagated to the binned alpha factor estimation. In the high mass region, they are obtained by the covariance matrix of the fit parameters of the sideband data $m_{ZZ}$ distributions. Additional systematic uncertainties are derived from comparisons between the nominal $Z +$ jets MC descriptions (exclusive LO samples with different associated parton multiplicities, and enriched in $b$ quark production, all produced with MADGRAPH5_AMC@NLO) and the merged MADGRAPH5_AMC@NLO simulations at NLO. The same background estimation methods are used to derive an alternative binned description of the $Z +$ jets background, and appropriate nuisance parameters, symmetrized around zero, describe the variation between the nominal and alternative estimation.

For the two dimensional $P_{\text{bkg}}^{DZjj}$ template shapes, two systematic uncertainties are considered for the signal samples: JES and JER variations, as well as comparison with identical MC samples where HERWIG++ [79] with EE5C tune [58] is used for parton showering and hadronization instead of PYTHIA. For background templates, a conservative systematic uncertainty from the limited size of the MC samples and the consequent smoothing procedure is derived by using alternative templates where the content of each two dimensional interval is replaced by the content of the preceding or following interval in $m_{ZZ}$. Background systematic uncertainties are validated in an “extended sideband region”, which includes the sideband region used in the analysis, as well as events failing the $\tau_{21}$ selection. At masses above 1 TeV, $1\sigma$ differences between data and simulation in this region are assigned as additional systematic uncertainties.

### 7.3 $X \rightarrow ZZ \rightarrow 2\ell 2\nu$

Various factors contribute to the experimental uncertainties that apply to processes derived from MC simulation. These include uncertainties in the trigger efficiency and lepton selection efficiencies. The effects of lepton momentum scale and JES are also taken into account and are propagated to the evaluation of $p_T^{\text{miss}}$. The uncertainties in the $b$ jet veto are estimated by measuring the $b$ tagging efficiency in data enriched in $t\bar{t}$ and are evaluated to be 2–4% for processes estimated from simulation, namely signal and WW, WZ events. Uncertainties due to the modeling of pileup are evaluated by varying the total inelastic cross section by $\pm 5\%$ around the nominal value.

Uncertainties in the background estimates based on control regions in data are estimated as described in section 6.2.3. For the Drell–Yan background a systematic uncertainty of 25% is combined with a statistical uncertainty from the size of the photon + jet control sample of 10% for the 0-jet and $\geq$1-jet categories, and of 50% for the VBF-tagged category. For the nonresonant background a 15% uncertainty is applied.
8 Results

The search for a scalar resonance $X$ decaying to $ZZ$ is performed over the mass range $130 \text{ GeV} < m_X < 3 \text{ TeV}$, where three final states are combined, $X \rightarrow ZZ \rightarrow 4\ell$, $2\ell 2q$, and $2\ell 2\nu$. Because of the different resolutions, efficiencies, and branching fractions, each final state contributes differently depending on the tested mass. The most sensitive final state between 130 and 500 GeV is $4\ell$ due to its best mass resolution, whereas in the intermediate region $500-700 \text{ GeV}$ $2\ell 2\nu$ is most sensitive, and for masses above 700 GeV $2\ell 2q$ is best.

In $X \rightarrow ZZ \rightarrow 4\ell$ and $2\ell 2q$, comparisons between the two dimensional ($m_{ZZ}, D_{bkg}^{Zjj}$) distributions observed in data and expected from the sum of background predictions are made. We set upper limits on the production cross section of the resonance by combining all the event categories in each analysis.

In $X \rightarrow ZZ \rightarrow 2\ell 2\nu$, using the resulting $m_T$ distributions, a shape based analysis is performed to extract the limits. The shapes of the signal and WZ, ZZ backgrounds are taken from MC simulation, those of Z + jets are taken from data, and for nonresonant backgrounds, the $\mu\mu$ control region is used to predict both shapes and normalizations of the $m_T$ distributions in the signal region, as described in section 6.2.

We follow the modified frequentist prescription described in refs. [80–82] (CL$_s$ method), and an asymptotic approach with the profile likelihood ratio as the test statistic is used for upper limits. Systematic uncertainties are treated as nuisance parameters and profiled using lognormal priors.

The width of the resonance $\Gamma_X$ is allowed to vary, starting from the narrow width approximation (denoted as $\Gamma_X = 0$) up to a large width. Production of the $X$ resonance is considered to be either in ggF or VBF, where VX production is included according to the relative expectation of the VX and VBF cross sections. No significant excess of events over the SM expectation is observed. Figure 10 shows upper limits at the 95% confidence level (CL) on the $pp \rightarrow X \rightarrow ZZ$ cross section $\times B_{X \rightarrow ZZ}$ as a function of $m_X$ for $\Gamma_X = 0$, 10, and 100 GeV.

The expected and observed limits on the pure VBF production cross section are better than the inclusive ones, because the background is smaller in the dedicated VBF categories. In general, limits are better when assuming a narrow width signal, since the signal over background ratio is higher. However, in the mass region below 300 GeV, interference effects with background are more complicated and play a role in the evolution of the limit as a function of $\Gamma_X$.

For $m_X < 2m_Z$, while the signal events are produced on shell around $m_X$ for $\Gamma_X \sim 0$, the majority of the events are produced off shell in the case of $\Gamma_X/m_X > 1\%$. Thus the relevant background is quite different when $\Gamma_X$ varies. In the ggF dominant category, for $130 < m_X < 140 \text{ GeV}$, the signal over background ratio is better in the relevant off shell region than in the on shell region, where signal events partly overlap with the H(125) peak. This makes the sensitivity better for a wide resonance. For $150 < m_X < 180 \text{ GeV}$, there is no overlap between the two on shell resonance peaks, so for a narrow resonance the signal over background ratio is larger and the limit is better. In the VBF category, the signal over background ratio is always smaller in the relevant off shell region compared to the on
shell region, yielding a better sensitivity for a wide resonance. The downward fluctuation in the VBF limit for $\Gamma_X = 10$ and 100 GeV, and $m_X < 180$ GeV, reflects an overall deficit of events in the VBF category in the off shell region of $m_4 > 200$ GeV.

Above the $2m_Z$ threshold, for $180 < m_X < 250$ GeV, the net interference of the ggF signal is positive around the peak, making the wide resonance sensitivity better. For the VBF signal, the enhancement from interference occurs at its right hand tail, where barely any background exists. This makes the limit for the wide VBF Higgs better in the range $m_X < 300$ GeV. Above that, the background drops rapidly and the limits for narrow and wide resonances are compatible.

Figure 11 shows the scan of the observed upper limits at the 95% CL, as a function of $m_X$ and $\Gamma_X/m_X$. The mass is scanned from 130 GeV to 3 TeV and the relative width from 0 to 30%. The results are provided with $f_{VBF}$ profiled and fixed to unity. The excluded product of the cross section and branching fraction ranges from 1.2 fb at 3 TeV to 402.6 fb at 182 GeV in the case of $f_{VBF}$ profiled, and from 1.0 fb at 3 TeV to 221.1 fb at 134 GeV in the VBF production mode.

9 Summary

A search for a new scalar resonance decaying to a pair of Z bosons is performed for a range of masses between 130 GeV and 3 TeV with the full data set recorded by the CMS experiment at 13 TeV during 2016 and corresponding to an integrated luminosity of 35.9 fb$^{-1}$. Three final states $ZZ \rightarrow 4\ell$, $2\ell 2q$, and $2\ell 2\nu$ are combined in the analysis, where $\ell = e$ or $\mu$. Both gluon fusion and electroweak production of the scalar resonance are considered with a free parameter describing their relative cross sections. A dedicated categorization of events based on the kinematic properties of the associated jets is used to improve the sensitivity of the search. A description of the interference between signal and background amplitudes for a resonance of an arbitrary width is included. No significant excess of events over the SM expectation is observed and limits are set on the product of the cross section and the branching fraction for its decay to ZZ for a wide range of masses and widths, and for different production mechanisms.

Acknowledgments

We thank Markus Schulze for optimizing the MCFM and JHUGen matrix element library for this analysis. We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centres and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: the Austrian Federal Ministry of Science, Research and Economy and the Austrian Science Fund; the Belgian Fonds de la Recherche Scientifique, and Fonds voor
Figure 10. Expected and observed upper limits at the 95% CL on the $pp \to X \to ZZ$ cross section as a function of $m_X$ and for several $\Gamma_X$ values with $f_{VBF}$ as a free parameter (left) and fixed to 1 (right). The results are shown for $4\ell$, $2\ell 2q$, and $2\ell 2\nu$ channels separately and combined. The reported cross section corresponds to the signal only contribution in the absence of interference.

Kansas State University, Manhattan, U.S.A.
A. Ivanov, K. Kaadze, Y. Maravin, A. Modak, A. Mohammadi, L.K. Saini, N. Skhirtladze

Lawrence Livermore National Laboratory, Livermore, U.S.A.
F. Rebasso, D. Wright

University of Maryland, College Park, U.S.A.

Massachusetts Institute of Technology, Cambridge, U.S.A.

University of Minnesota, Minneapolis, U.S.A.

University of Mississippi, Oxford, U.S.A.
J.G. Acosta, S. Oliveros
University of Nebraska-Lincoln, Lincoln, U.S.A.

State University of New York at Buffalo, Buffalo, U.S.A.
A. Godshalk, C. Harrington, I. Iashvili, D. Nguyen, A. Parker, S. Rappoccio, B. Roozbahani

Northeastern University, Boston, U.S.A.

Northwestern University, Evanston, U.S.A.

University of Notre Dame, Notre Dame, U.S.A.

The Ohio State University, Columbus, U.S.A.

Princeton University, Princeton, U.S.A.

University of Puerto Rico, Mayaguez, U.S.A.
S. Malik, S. Norberg

Purdue University, West Lafayette, U.S.A.

Purdue University Northwest, Hammond, U.S.A.
T. Cheng, J. Dolen, N. Parashar

Rice University, Houston, U.S.A.

University of Rochester, Rochester, U.S.A.
A. Bodek, P. de Barbaro, R. Demina, Y.t. Duh, T. Ferbel, M. Galanti, A. Garcia-Bellido, J. Han, O. Hindrichs, A. Khukhumaishvili, K.H. Lo, P. Tan, M. Verzetti

The Rockefeller University, New York, U.S.A.
R. Ciesielski, K. Goulianos, C. Mesropian
Rutgers, The State University of New Jersey, Piscataway, U.S.A.

University of Tennessee, Knoxville, U.S.A.
A.G. Delannoy, J. Heideman, G. Riley, K. Rose, S. Spanier, K. Thapa

Texas A&M University, College Station, U.S.A.

Texas Tech University, Lubbock, U.S.A.

Vanderbilt University, Nashville, U.S.A.

University of Virginia, Charlottesville, U.S.A.
M.W. Arenton, P. Barria, B. Cox, R. Hirosky, M. Joyce, A. Ledovskoy, H. Li, C. Neu, T. Sinthuprasith, Y. Wang, E. Wolfe, F. Xia

Wayne State University, Detroit, U.S.A.

University of Wisconsin - Madison, Madison, WI, U.S.A.

†: Deceased
1: Also at Vienna University of Technologies, Vienna, Austria
2: Also at IRFU, CEA, Université Paris-Saclay, Gif-sur-Yvette, France
3: Also at Universidade Estadual de Campinas, Campinas, Brazil
4: Also at Federal University of Rio Grande do Sul, Porto Alegre, Brazil
5: Also at Universidade Federal de Pelotas, Pelotas, Brazil
6: Also at Université Libre de Bruxelles, Bruxelles, Belgium
7: Also at Institute for Theoretical and Experimental Physics, Moscow, Russia
8: Also at Joint Institute for Nuclear Research, Dubna, Russia
9: Also at Cairo University, Cairo, Egypt
10: Now at Ain Shams University, Cairo, Egypt
11: Also at Fayoum University, El-Fayoum, Egypt
12: Now at British University in Egypt, Cairo, Egypt
13: Also at Department of Physics, King Abdulaziz University, Jeddah, Saudi Arabia
14: Also at Université de Haute Alsace, Mulhouse, France
15: Also at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia
16: Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland
17: Also at RWTH Aachen University, III. Physikalisches Institut A, Aachen, Germany
18: Also at University of Hamburg, Hamburg, Germany
19: Also at Brandenburg University of Technology, Cottbus, Germany
20: Also at MTA-ELTE Lund+dlet CMS Particle and Nuclear Physics Group, Eötvös Loránd University, Budapest, Hungary
21: Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary
22: Also at Institute of Physics, University of Debrecen, Debrecen, Hungary
23: Also at Indian Institute of Technology Bhubaneswar, Bhubaneswar, India
24: Also at Institute of Physics, Bhubaneswar, India
25: Also at Shoolini University, Solan, India
26: Also at University of Visva-Bharati, Santiniketan, India
27: Also at University of Ruhuna, Matara, Sri Lanka
28: Also at Isfahan University of Technology, Isfahan, Iran
29: Also at Yazd University, Yazd, Iran
30: Also at Plasma Physics Research Center, Science and Research Branch, Islamic Azad University, Tehran, Iran
31: Also at Università degli Studi di Siena, Siena, Italy
32: Also at INFN Sezione di Milano-Bicocca; Università di Milano-Bicocca, Milano, Italy
33: Also at International Islamic University of Malaysia, Kuala Lumpur, Malaysia
34: Also at Malaysian Nuclear Agency, MOSTI, Kajang, Malaysia
35: Also at Consejo Nacional de Ciencia y Tecnología, Mexico city, Mexico
36: Also at Warsaw University of Technology, Institute of Electronic Systems, Warsaw, Poland
37: Also at Institute for Nuclear Research, Moscow, Russia
38: Also at National Research Nuclear University 'Moscow Engineering Physics Institute' (MEPhI), Moscow, Russia
39: Also at St. Petersburg State Polytechnical University, St. Petersburg, Russia
40: Also at University of Florida, Gainesville, U.S.A.
41: Also at P.N. Lebedev Physical Institute, Moscow, Russia
42: Also at California Institute of Technology, Pasadena, U.S.A.
43: Also at Budker Institute of Nuclear Physics, Novosibirsk, Russia
44: Also at Faculty of Physics, University of Belgrade, Belgrade, Serbia
45: Also at INFN Sezione di Pavia; Università di Pavia, Pavia, Italy
46: Also at University of Belgrade, Faculty of Physics and Vinca Institute of Nuclear Sciences, Belgrade, Serbia
47: Also at Scuola Normale e Sezione dell'INFN, Pisa, Italy
48: Also at National and Kapodistrian University of Athens, Athens, Greece
49: Also at Riga Technical University, Riga, Latvia
50: Also at Universität Zürich, Zurich, Switzerland
51: Also at Stefan Meyer Institute for Subatomic Physics (SMI), Vienna, Austria
52: Also at Adiyaman University, Adiyaman, Turkey
53: Also at Istanbul Aydin University, Istanbul, Turkey
54: Also at Mersin University, Mersin, Turkey
55: Also at Piri Reis University, Istanbul, Turkey
56: Also at Gaziosmanpasa University, Tokat, Turkey
57: Also at Izmir Institute of Technology, Izmir, Turkey
58: Also at Necmettin Erbakan University, Konya, Turkey
59: Also at Marmara University, Istanbul, Turkey
60: Also at Kafkas University, Kars, Turkey
61: Also at Istanbul Bilgi University, Istanbul, Turkey
62: Also at Rutherford Appleton Laboratory, Didcot, United Kingdom
63: Also at School of Physics and Astronomy, University of Southampton, Southampton, United Kingdom
64: Also at Monash University, Faculty of Science, Clayton, Australia
65: Also at Instituto de Astrofísica de Canarias, La Laguna, Spain
66: Also at Bethel University, ST. PAUL, U.S.A.
67: Also at Utah Valley University, Orem, U.S.A.
68: Also at Purdue University, West Lafayette, U.S.A.
69: Also at Beykent University, Istanbul, Turkey
70: Also at Bingol University, Bingol, Turkey
71: Also at Erzincan University, Erzincan, Turkey
72: Also at Sinop University, Sinop, Turkey
73: Also at Mimar Sinan University, Istanbul, Istanbul, Turkey
74: Also at Texas A&M University at Qatar, Doha, Qatar
75: Also at Kyungpook National University, Daegu, Korea
